PUBLIC HEALTH REPORTS

VOL. 43 JANUARY 6, 1928 NO. 1

PREVALENCE OF POLIOMYELITIS IN THE UNITED STATES

Reports from the health officers of 43 States for the four weeks ended December 24, 1927, show decreases in the number of cases of poliomyelitis as follows:

	Cases
Week ended December 3, 1927	195
Week ended December 10, 1927	163
Week ended December 17, 1927	118
Week ended December 24, 1927	85

Twenty-four of the cases reported for the week ended December 24 were in the Pacific Coast States. Massachusetts reported 11 cases for that week, Michigan and New York each reported 5 cases, Texas reported 6, and Pennsylvania 4 cases. No other State reported more than three cases of poliomyelitis for the week.

A comparison of the reports for the week ended December 24, 1927, with those for the corresponding weeks of the years 1925 and 1926 shows that poliomyelitis is more prevalent than it usually is in December The following table is based on reports from 42 States:

	Cases
Week ended December 26, 1925	12
Week ended December 25, 1926	12
Week ended December 24, 1927	85

ALASTRIM AND SMALLPOX POTENCY OF SMALLPOX VACCINE

HYGIENIC LABORATORY BULLETIN NO. 149

Hygienic Laboratory Bulletin No. 149, containing two papers which will be of interest to health officers, will soon be issued. It will be on sale by the Superintendent of Documents, Government Printing Office, at 35 cents per copy

The immunological relationship of alastrim and mild smallpox. By James P. Leake and John N. Force Hygienic Laboratory Bulletin 149.

This paper presents the results of some experiments which tend to show the identity of an eruptive disease prevalent in tropical America with the mild smallpox of the United States and Canada. This disease travels under a variety of names, such as varioloid varicella,

alastrim, Kaffir milk pox, Sanaga pox, the Australian disease, Cuban itch, Philippine itch, and so on.

In order to test the relationship of alastrim with mild smallpox, a considerable number of experiments were performed upon monkeys and rabbits. As a result of these immunological tests the authors conclude that the fact that a definite cross-immunity exists between alastrim and mild smallpox, and between alastrim and vaccine virus, is additional evidence of the identity of the two diseases.

A method for estimating the potency of smallpox vaccine. By John N. Force and James P. Leake. Hygienic Laboratory Bulletin No. 149.

It has been held that the potency of smallpox vaccine is self-evident in use and that vaccine of low potency, by the natural process of selection, would be forced off the market. Unfortunately, this has not proved to be the case. Many vaccinations are performed without adequate observation of the results and physicians have had to be content to accept a considerable percentage of failures in vaccination, notwithstanding various methods of vaccination.

In this paper the authors devote attention to the vaccine itself rather than to the manner of administering it, and describe a method of estimating its potency. As a result of their experiments they lay down the criterion that a smallpox vaccine of high potency, when diluted 1 to 1,000, should produce a confluent eruption on from 90 to 100 per cent of the vaccinated area on the back of a rabbit and when diluted 1 to 3,000 the decrease in confluence should not be over 20 per cent. They state that a vaccine satisfying this criterion should produce in all previously unvaccinated persons a circular vesicle measuring at least 7 mm. in diameter on the seventh day when applied undiluted to a circle of the exposed derma measuring 2 mm. in diameter.

THE EIGHTH PAN AMERICAN SANITARY CONFERENCE

Official Report of Resolutions Adopted

(*Acta Final*)

The Eighth Pan American Sanitary Conference initiated its work in the city of Lima on October 12, 1927, at a formal session presided over by the Hon. Pedro José Rada y Gamio, Minister of Foreign Relations of the Republic of Peru, who made the opening address. The delegates of the Republics represented in the conference made appropriate responses, and the temporary chairman of the conference, Dr. Carlos Enrique Paz Soldán, delivered the closing speech of the session.

The first general session of the conference was held on October 13, 1927, Dr. Carlos Enrique Paz Soldán, temporary chairman, presiding.

In conformity with the rules and regulations, the delegates proceeded to elect the permanent president of the conference, and, on motion of the delegates of Uruguay and of the United States of America, Doctors González and Cumming, respectively, Dr. Carlos Enrique Paz Soldán, who had been designated temporary president by the former conference, held in Habana, was unanimously elected. In like manner Dr. Baltazar Caravedo was elected secretary general of the conference.

In compliance with the provisions of the second paragraph of the second article of the rules and regulations, the selection by lot to determine the numerical order of the delegations was effected and resulted as follows:

1. Colombia.
2. Honduras.
3. Panama.
4. Paraguay.
5. United States of America.
6. Guatemala.
7. Bolivia.
8. Dominican Republic.
9. Costa Rica.
10. Venezuela.
11. Haiti.
12. Uruguay.
13. Ecuador.
14. Argentina.
15. Cuba.
16. Brazil.

Drs. Bolivar J. Lloyd, Bento Oswaldo Cruz, and Alfredo Sordelli were elected secretaries of the conference.

The conference resolved to appoint the following committees, apportioning the topics of the program among them in the manner indicated below:

The first committee, entitled "Executive committee and committee on credentials."

The second committee, entitled "Committee on the Pan American Sanitary Code," was assigned topics 1, 17, 25, 26, and 27.

The third committee, entitled "Committee on sanitary organization of the Pan American States," was assigned topics 2, 3, 4, 5, 6, 8, 16, 21, and 29.

The fourth committee, entitled "Committee on epidemiology, sanitation, and prophylaxis," was assigned topics 7, 9, 10, 11, 12, 13, 14, 15, 18, 19, 20, 22, 23, and 24.

After a report made by the secretary general, Dr. Baltazar Caravedo, the conference definitely approved the credentials of the following-named delegates:

Argentina: Drs. Laurentino Olascoaga, Nicolás Lozano, and Alfredo Sordelli.

Bolivia: Drs. Adolfo Flores and Adolfo Durán.

Brazil: Drs. João Pedro de Albuquerque and Bento Ozwaldo Cruz.

Colombia: Dr. Julio Aparicio.

Costa Rica: Dr. Solón Núñez F.

Cuba: Drs. Fernando Renseli and Mario G. Lebredo.

Ecuador: Dr. Luis M. Cueva.

The United States of America: Drs. Hugh S. Cumming, Bolivar J. Lloyd, and John D. Long.

Guatemala: Mr. Pablo Emilio Cuedes.

Haiti: Mr. Victor Kieffer Marchand.

Honduras: Dr. José Jorge Callejas.

Panama: Dr. José Guillermo Lewis.

Paraguay: Dr. Isidro Ramírez.

Peru: Drs. Carlos Enrique Paz Soldán, Sebastian Lorente, Baltazar Caravedo, Daniel E. Lavarería, and Julio C. Castiaburú.

Dominican Republic: Drs. Ramón Báez Soler and Alejandro Bussalleu.

Uruguay: Dr. Justo F. González.

The United States of Venezuela: Dr. Emilio Ochoa.

The conference unanimously resolved to designate as honorary presidents the Chief Executives of the nations represented.

There were accepted in subsequent sessions, Dr Julio C. Castiaburú as delegate for Nicaragua (that country ranking 17 in numerical order), Dr. Guillermo Angulo Puente Arnao as delegate of Haiti, and Mr. Jaime G. Bennett as delegate of Costa Rica.

The Eighth Pan American Sanitary Conference discussed and adopted the following motions, resolutions, and conventions, namely:

1. The American delegation, assembled in Lima on the occasion of the convening of the Eighth Pan American Sanitary Conference, express their thanks and appreciation to the President of the Republic of Peru, the Honorable Augusto B. Leguía, for the splendid manifestations of hospitality which he has shown them and for the extraordinary progress which has been made in the establishment, materially, of the basic principles of hygiene and sanitation in the Republic of Peru during his administration.

2. The American delegation, assembled in Lima on the occasion of the convening of the Eighth Pan American Sanitary Conference, extend a vote of thanks to the president of the conference, Prof. Carlos Enrique Paz Soldán, for the laudable manner in which he has directed the debates and the work of the conference, and to the organizing committee for the splendid organization effected, and request that this vote be transmitted to the Chancellery of Peru.

3. The Eighth Pan American Sanitary Conference approves the following:

Memorandum Concerning the Interpretation of the Pan American Sanitary Code

By dangerous or contagious disease, referred to in the latter part of article 4 of the Code, is understood all diseases of an epidemic character.

Let it be understood that the obligation to notify "adjacent countries" means all of the American Republics.

With reference to article 9, it shall be understood that the sanitary measures referred to are to be applied to vessels from the infected area.

In the interpretation of articles 11 and 30, it is understood that article 11 refers to the scientific definition of an infected area and article 30 to the standard prescribed by the Pan American Sanitary Code which the sanitary authorities should follow.

Where article 29 reads "autochthonous cases" this should be understood to mean one or more cases.

That in the interpretation of article 35, it is understood that a "clean ship" is one coming from a clean port of class A or B, which, during its voyage, has not had aboard any case of bubonic plague (including rodent plague), cholera yellow fever, smallpox, typhus fever, or any other disease of an epidemic character, and which vessel has strictly complied with the requirements contained in this Code.

Concerning article 41, inset 5, and article 44, inset 3, which refer to human or rodent plague and to smallpox, respectively, it is understood that there is no objection to the application of the measures which the local sanitary authorities may decide upon in each case in view of the special circumstances.

That in cases of doubtful interpretation of the articles of this Code which refer to the application of sanitary measures to vessels, consideration shall be given to the actual conditions found on the vessel in preference to conditions at the ports where the vessel has called.

4. The Eighth Pan American Sanitary Conference reminds all the signatory powers of their obligation to adopt the model bill of health to which article 16 of the Code refers.

5. The Eighth Pan American Sanitary Conference suggests to the signatory or adhering nations the expediency of naming in all ports of entry an official body whose duty it shall be to determine the diagnosis in doubtful cases of contagious disease.

6. The Eighth Pan American Sanitary Conference recommends to the Pan American Sanitary Bureau that it undertake to interest naval architects, and commercial organizations engaged in building or operating vessels, in the rat-proofing of vessels, this to be done in the interest of the organization concerned.

7. The Eighth Pan American Sanitary Conference recommends to the Governments of the American countries the construction of rat-proof wharves—that is to say, wharves of steel and cement—and also that the freight in warehouses be carefully elevated 1 foot above the floor and placed in separate sections in order to leave free spaces for easily guarding against rodents.

8. The Eighth Pan American Sanitary Conference, considering that mortality statistics constitute the fundamental basis of our knowledge of the sanitary conditions of the peoples of America, especially recommends that the Pan American Sanitary Bureau endeavor to put in operation as soon as possible the plan suggested by the Pan American Scientific Congress, assembled in Lima in 1924, namely, that it take appropriate action to the end that all the countries of America which have not already done so adopt the classification of the causes of death now in use in the United States of North America (convention of Paris of 1920), with its methods and procedure, in the compilation of statistics, in order to be able to determine in a systematic manner the comparable mortality rates of the different countries.

9. The Eighth Pan American Sanitary Conference, considering that the placing of sanitary inspectors on vessels, both on the Atlantic and the Pacific coasts, has proved of benefit in facilitating the application of prophylactic measures in the case of vessels calling at infected ports, recommends to the Governments of the American Republics that such inspectors be so placed by any country desiring to do so, and in conformity with its laws and regulations governing the case.

10. The Eighth Pan American Sanitary Conference very respectfully requests of the signatory Governments the faithful observance of articles 3, 4, and 5 of the Pan American Sanitary Code, which constitute the basis of international defense against epidemic diseases of a grave character.

11. The Eighth Pan American Sanitary Conference declares that habit-forming drugs constitute a grave danger to the future of the countries of the American Continent because of their easy dissemination and their pernicious effects on the race, and recommends to the governments of the different States the organization of social defense against habit-forming drugs, establishing repressive, fiscal, therapeutic, and prophylactic measures on the following bases:

(a) Reduction of the cultivation, manufacture, and sale of narcotics, limiting their use to therapeutic necessities and in accordance with the regulations of the sanitary authorities of each country, which shall fix the penalties incurred by infractors;

(b) Reporting of addicts and obligatory treatment in special establishments under restraint, supported by the State and in charge of medical specialists; and

(c) Prophylaxis should also be carried on by education and antinarcotic propaganda.

12. The Eighth Pan American Sanitary Conference reiterates its adherence to that principle of reform of governmental procedure which will prepare the State for the adoption of a definite public policy in matters of hygiene, and declares that only by the establishment of a department dedicated exclusively to medico-social problems

is it possible to make effective to the fullest extent a national or international policy of hygiene and sanitation; consequently, it is recommended that those Governments which have not yet done so should create a department or ministry of health.

13. The Eighth Pan American Sanitary Conference again reaffirms that, for the eradication of bubonic plague, it is necessary to study the complex local problems that its endemo-epidemic character offers in order to determine with precision the factors which contribute to its genesis;

That while these investigations are being made, the campaign against plague should tend to a realization of measures of security against rodents, particularly the rat-proofing of vessels, of dwellings, and, in general, all temporary or permanent habitations of man

The conference recognizes that the destruction of rats can and ought to be continued without cessation, in the hope of reducing their number and subjecting these rodents to biologic control;

That to protect man against the spread of bubonic plague, such biologic control may be usefully employed; and

That this work ought to be done by a central supervising agency.

14. The Eighth Pan American Sanitary Conference, with the object of determining the development and extent of intestinal parasitism on this Continent, recommends to the sanitary institutions of the countries of the Pan American Union that they send reports of such works as are officially recognized as important to the Pan American Sanitary Bureau, which will undertake to outline the geographic distribution of the various intestinal parasites of America.

15 The Eighth Pan American Sanitary Conference recommends to the American Governments that they cooperate by means of laws, decrees, or resolutions in campaigns throughout the entire Continent against venereal diseases, and most respectfully urges said Governments to endeavor by these means to lessen prostitution

That there be established free official clinics for venereal disease, provided with a complete stock of medical supplies, where the public may find treatment within its reach, in order that by this measure the spread of venereal disease may be restricted

16. The Eighth Pan American Sanitary Conference, bearing in mind the participation of the Governments of the American Republics in the International Sanitary Conference held in Paris in June, 1926, to revise the International Sanitary Convention of 1912, is of the opinion that the Pan American Sanitary Bureau should assume and fulfill the duties and obligations of a regional agency for the collection of reports of communicable disease and for the transmission of these reports to the Governments affiliated with the Pan American Union and to the Office International de Hygiène Publique of Paris.

17. The Eighth Pan American Sanitary Conference, in view of the progress attained in the combating of tuberculosis in the different countries and of the experimental methods of immunity now employed, recommends to the Governments that, through the intermediary of their sanitary institutions, they periodically send to the Pan American Sanitary Bureau all data relating to vaccination against tuberculosis, it being the duty of said bureau to summarize the results reported at the next meeting of this conference.

18. The Eighth Pan American Sanitary Conference suggests to the American Governments that they consider the question of prenuptial examination as an adjunct to the prophylaxis of venereal diseases.

19. The Eighth Pan American Sanitary Conference declares that the health and welfare of the laboring class is intimately related to the public health and to the economic development of a country, and that the losses sustained in industry as a result of associated disease cause serious harm to the nation, diminish the actual output of labor, and, above all, are a detriment to the future growth and development of the population, undermining its health, for which reason the conference recommends to the different countries of America the necessity of establishing special agencies within departments of health which shall have charge of everything relating to sanitation in industry in order to place laborers in the best possible environment consistent with their mental and physical capabilities.

20. The Eighth Pan American Sanitary Conference declares that alastrim, so long as its nature is not definitely determined, shall be considered, in so far as international sanitary measures are concerned, the same as smallpox.

21. The Eighth Pan American Sanitary Conference recommends to the American countries that they establish a mutual interchange of all rules, regulations, laws, and sanitary orders, and of all authoritative reports that may be of interest to other countries, sending copies of them to other Republics and, likewise, to the Pan American Sanitary Bureau.

22. The Eighth Pan American Sanitary Conference, in view of the evident desire which exists of holding meetings from time to time of the officers and members of the Pan American Sanitary Bureau, as occasion may require, resolves:

(*a*) That meetings of these officers and members be held in Washington, on call of the director and at intervals of 1 year to 18 months, as circumstances may require; and be it further

Resolved, That hereafter the actual and necessary expenses and the traveling expenses of the members of the Pan American Sanitary Bureau may be paid out of the funds of the Pan American Sanitary Bureau, including a per diem during the period of the conference, an expense which shall not exceed $10 per day, United States currency.

(b) When, in the discretion of the director, a member or representative of the Sanitary Bureau is required to perform any official duty away from his place of residence, the director is authorized to pay out of the funds of the bureau the necessary traveling and other expenses of said representative member, including a per diem, as provided for in paragraph (a) which precedes, during the time in which he is not engaged in travel.

It is understood that salaries shall be paid by the government of the member or representative.

23 The Eighth Pan American Sanitary Conference resolves that, in view of the evident necessity for more direct contact and more perfect interchange of information between the sanitary authorities of the American Republics, there should be established, and there is hereby established, the position of traveling representative, and the incumbent shall be a member ex officio of the Pan American Sanitary Bureau and shall be appointed by the director from among the members of the public health services of the various Republics for such periods of time as the director may deem necessary for the service of the bureau.

24. The Eighth Pan American Sanitary Conference recommends for the study and consideration by the ninth conference the subject of hospital organization as administered in America, and suggests to the Pan American Sanitary Bureau the expediency of preparing a systematic compilation of data obtained from sanitary authorities concerning the status of hospital administration on the American Continent.

25. The Eighth Pan American Sanitary Conference, because of the importance of the subject and in view of the favorable results which have followed the application of modern measures, especially Pasteurization, for the safeguarding of milk, and considering the reduction in infant mortality and also the reduction in mortality in general which have followed the utilization of such measures, recommends to the various Governments that the matter of the safeguarding of milk and the scientific measures for rendering it safe be considered as of paramount importance. In order to secure, in the shortest time possible, the reduction in the number of cases of the various diseases that may be conveyed by milk, it is recommended that the Ninth Pan American Sanitary Conference undertake the drafting of a model law for the safeguarding of this important food.

26. The Eighth Pan American Sanitary Conference, having taken cognizance of the proposed rules and regulations concerning the safeguarding of milk which the special committee appointed by the Peruvian Government has prepared, takes pleasure in declaring that, from a scientific point of view, they fulfill the requirements of safety.

27. The Eighth Pan American Sanitary Conference reiterates its recommendation that in departments of health there be constituted a personnel trained in the work of health and sanitation and selected on the basis of the most perfect fitness, and that there be provided the stimulus of legitimate and gradual promotion in said career, and at the same time recommends the establishment of institutes of hygiene and social medicine for the accomplishment of this object.

28. The Eighth Pan American Sanitary Conference insists on calling the attention of the American Governments to the expediency of continuing the campaign against alcoholism in the manner best adapted to the requirements of each country.

29. The Eighth Pan American Sanitary Conference suggests that for future conferences the Pan American Sanitary Bureau solicit from the Governments of the signatory countries a list of subjects of special interest - a list which should be received by the Pan American Sanitary Bureau at least 18 months before the meeting of the next conference. The said bureau shall examine and classify the subjects proposed, formulating a program of the most important topics, judging from the number of countries that may have submitted them. This program shall be sent to the Governments for their consideration at least one year before the meeting of the ninth conference. On holding the ninth conference, each delegate shall read a résumé of not more than two pages of ordinary paper on the topics of the program which may interest him, without prejudice to his submitting complete observations on the same questions, which observations shall be delivered to the office of the chairman of the conference.

30. The Eighth Pan American Sanitary Conference, having in mind that certain countries of America are giving marked attention to conditions concomitant with their courses in public instruction, including such subjects as (1) the hygienic conditions found in school buildings, (2) teaching methods, (3) sanitary inspection, recommends to all Governments that, considering the social and economic importance of school hygiene in general, they send to the Pan American Sanitary Bureau one year prior to the meeting of the Ninth Pan American Sanitary Conference such reports and instructions as they deem expedient regarding the adoption of measures of reform or of procedure relating to the hygiene of schools, to the end that this subject may be made one of the topics for study by the ninth conference.

Additional Protocol Approved by the Conference (Ad Referendum)

The ratification of the Sanitary Code shall be deposited in the office of the Secretary of State of the Republic of Cuba, and the Cuban Government shall communicate these ratifications to the other signatory States, which communication shall constitute exchange of ratifications. The convention shall become effective in

each of the signatory States on the date of ratification thereof by said State, and shall remain in force without limitation of time, each one of the signatory or adherent States reserving the right to withdraw from the convention by giving in due form a year's notice in advance to the Government of the Republic of Cuba.

The conference, in the session of October 19, 1927, proceeded to designate the seat of the Ninth Pan American Sanitary Conference, having unanimously chosen the city of Buenos Aires, Argentina, as the meeting place of the conference.

The conference proceeded to elect the officers and members of the Pan American Sanitary Bureau of Washington, the following being unanimously elected:

Honorary director, Dr. Carlos Enrique Paz Soldán.
Director, Dr. Hugh S. Cumming.
Vice director, Dr. Mario G. Lebredo.
Secretary, Dr. Sebastián Lorente.
Members, Dr. Solón Núñez F., Dr. Ramón Báez Soler, Dr. Justo F. González, Dr. João Pedro de Albuquerque.

The closing session of the conference was held on the evening of October 20, 1927, Dr. Carlos Enrique Paz Soldán, presiding. At this meeting Drs. Fernando Rensoli and Luis M. Cueva, delegates for Cuba and Ecuador, respectively, and the chairman of the Peruvian delegation, Dr. Sebastián Lorente, made addresses, their remarks being included in the proceedings of the conference.

Done and signed in the city of Lima on the 20th day of the month of October, 1927, and a certified copy delivered to each of the delegations for transmission to their respective countries, a copy to be sent through diplomatic channels to the Department of Foreign Relations of Peru and to the Pan American Sanitary Bureau in Washington.

(Signed) CARLOS ENRIQUE PAZ SOLDÁN,
Chairman of the Conference.

(Signed) BALTAZAR CARAVEDO,
Secretary General of the Conference.

THE FOOD OF CULICINE LARVÆ

FOOD ORGANISMS IN PURE CULTURE

By M. A. BARBER, *Special Expert, United States Public Health Service*

In a previous article (1) I described some experiments on the food of anopheline larvæ where food organisms in pure culture were supplied to larvæ hatched from sterilized eggs. It was demonstrated by these experiments that *Anopheles* may be reared to maturity on bacteria alone, infusoria alone, or algæ alone, provided living food

organisms were supplied them. In the present work I have attempted to repeat with culicine larvæ the same sort of experiments.

The method of sterilizing the eggs of culicines was essentially the same as that employed for *Anopheles* except that eggs united in boats were dissected apart before applying the germicide. Eggs were placed on a sterile cloth spread in a tin spoon perforated by many small holes. Eighty per cent ethyl alcohol was dripped over the eggs for three to five minutes. The eggs were then dried on the cloth to insure their floating when transferred to a liquid medium. The dried eggs were then placed in test tubes containing sterile nutrient broth or sloped agar, a few to each test tube. Larvæ hatched from the eggs were left in the medium for a time, and those which had apparently remained sterile were pipetted to flasks or other larger receptacles containing sterile media suitable for the larvæ and for the living food organisms to be tested.

I obtained culicine eggs by confining gravid females in cages over water or from pools and other waters where egg boats were laid under natural conditions. In some cases receptacles containing rain water were set out and examined daily in order to obtain eggs the day after they were laid.

The eggs withstood the process of sterilization well, as was indicated by the large percentage hatching out after treatment. In one series where eggs of *Culex quinquefasciatus* were treated for five minutes with 80 per cent alcohol and subsequently dried, every one of 124 hatched when transferred to broth or agar. Even eggs that were so far developed that larvæ hatched out within an hour or two after sterilization were apparently unhurt by the alcohol.

A part of the test tubes to which parcels of treated eggs were transferred showed contamination promptly, the proportion of contaminated tubes varying in the different batches. Generally, eggs laid in egg boats gave a larger proportion of contaminated cultures than those laid separately.

In many tubes, however, no contamination appeared although cultures were kept for weeks on a considerable variety of media adapted for bacterial growth. Eggs or young larvæ were tested in glucose and serum broth, on and under the surface of various agars, in anaerobic as well as in aerobic cultures, and at temperatures varied to suit different kinds of contaminants. So far as ordinary bacterial tests can show, sterilization was complete.

Eggs hatched in both acid and alkaline media. Those of *C. quinquefasciatus* hatched in a medium of pH 6.4 and one of 9.4; of *Aedes aegypti*, in pH 6.2 and 8.6, *C. quinquefasciatus* hatched in a medium containing 0.7 per cent salt as well as in ordinary media.

Oxygen appeared to be essential to the hatching of the eggs of the culicine species tested. Eggs embedded in agar or placed in broth

recently boiled under vaseline failed to hatch. Moisture was, of course, essential; but eggs in some tests hatched on the surface of a comparatively dry agar, where they remained dormant until wetted.

Atkin and Bacot (2) have reported experiments where the presence of living bacteria, yeast or molds proved an important, though not necessary, stimulus to the hatching of the eggs of *Aedes ægypti*. In my experiments there was no indication that bacteria promoted hatching in either *C. quinquefasciatus* or *A. ægypti*. Eggs hatched out in water or in clear sterile media as promptly as in contaminated cultures. In a few cases bacteria seemed to encourage the hatching of eggs of *A. sollicitans*, but they were surely not a necessary stimulus. It is true that in my experiments eggs before sterilization usually lay for various periods of time in nonsterile water, in the case of "ripe" egg boats for several days; in other cases they remained only a few hours in clear water, where it seems unlikely that they could have been affected by bacterial growth acting on them before sterilization.

On the other hand, the presence of bacteria in heavily contaminated cultures or of a thick growth of infusoria, bacteria, or yeasts sown in the cultures did not inhibit hatching. Eggs of *C. quinquefasciatus* hatched and the larvæ lived some days almost embedded in a bacterial growth at the bottom of an agar tube.

In a large proportion of the cultures, eggs of *C. quinquefasciatus* and of *A. ægypti* hatched within two or three days after they were laid. In only one or two cases, however, did the eggs of *Aèdes sollicitans* hatch in the media in which they were sown. In one series of 28 tubes, hatching occurred in only one, a control in which the eggs were not sterilized and in which the larvæ appeared in about 10 days. Two weeks after the eggs were sown, bacteria were transferred from this control to seven other tubes of the same batch in which eggs remained unhatched and sterile. In all these tubes hatching was observed on the following day, but it occurred also in three tubes which had not been inoculated with bacteria. Possibly all cultures had been affected by a rise in temperature which occurred at that time.

In another series, eggs of *A. sollicitans* were sterilized and placed on moist sterile earth or sand in test tubes. One month later they were wetted with a medium containing 0.7 per cent NaCl. Five out of nine hatched. Eggs placed in test tubes without earth or sand failed to hatch when wetted with the same medium. It would appear that a resting period of some days favored the hatching of the eggs of this species, but a long resting period was not essential. The presence of bacteria was not a necessary stimulus. Eggs hatched in 0.7 per cent NaCl and in sterilized pool water to which no salt had been added.

Eggs of *Aëdes thibaulti* and of a *Psorophora* (probably *horridus*) failed to hatch although freshly laid and presumably viable. They were placed on a great variety of media, some with bacteria and some sterile, and, in the case of *A. thibaulti*, some with living algæ. The cultures were kept under observation for several weeks.

As in the case of *Anopheles* larvæ, the presence of living food organisms seemed to be necessary to any considerable growth. Larvæ survived a long time in sterile broth; those of *A. quinquefasciatus* for 13 days and of *A. ægypti* for at least 12 days. In neither case did any considerable growth appear. Growth in contaminated cultures was almost invariably better than in sterile ones. Where cultures of bacteria or infusoria were inoculated with the eggs, larvæ showed better growth than in sterile controls in the same medium. The addition of dead microorganisms or of dead organic matter to cultures did not materially promote growth of larvæ. Eggs of *C. quinquefasciatus* hatched in a medium consisting of 0.7 per cent NaCl solution plus human blood cells, but the larvæ did not grow although red blood cells were seen in their intestines.

Culicines reached maturity in media contaminated with bacteria or inoculated with various living microorganisms, and many emergences occurred in test tubes of the ordinary size They throve better than did *Anopheles* in small containers containing a rich medium. But, like *Anopheles*, they found more favorable conditions in such containers as 250 or 500 cubic centimeter Erlenmeyer flasks, pint Mason jars, or large test tubes supplied with a larger amount of a medium less concentrated but sufficiently rich to grow the microorganisms. A very favorable medium consisted of algæ which had been allowed to rot several days at high room temperature, then mixed with water and autoclaved. To this was added a small percentage of nutrient broth, often introduced with the larvæ and with the living microorganisms. The flasks were plugged with cotton and the Mason jars provided with a special cover to exclude bacteria.

The microorganisms used as food for the larvæ were isolated by the single-cell method, or, in the case of some of the bacteria, by plating out. The alga *Scenedesmus*, and the infusorian *Colpidium*, employed in the pure cultures, were the same strains as those used in the experiments with *Anopheles* (1). After the emergence of the adult culicines the cultures were tested for purity by microscopic examination and by transfer of considerable amounts to nutrient media favorable for the growth of contaminants.

A brief description follows of the experiments in which mosquitoes bred on pure cultures of microorganisms emerged living and capable of flight. I must make the same reservation in regard to the purity of the cultures that I made in the case of the *Anopheles*. It is always possible that some contaminant may have been present but failed to

grow on the test media or may have died out during the development of the larvæ. But it is highly probable that the effective microorganism was the one originally inoculated and alone found living at the close of the experiment.

1. *Yeast.*—Fleischmann's yeast was isolated in pure culture and inoculated at the same time with the eggs of *C. quinquefasciatus* into a medium consisting of a meat-extract-peptone-glucose broth diluted with 2 parts of water. About 10 cubic centimeters of the medium was contained in a test tube of ordinary size and kept at high room temperature. Twenty-two days after the hatching of the eggs one small adult emerged. Only yeast appeared in the medium examined microscopically after emergence and in a test culture on agar. In another culture a large amount of pure culture of living yeast was added to sterile water. In this the yeast cells died or became dormant. Growth of larvæ was inconsiderable in this medium. Apparently actively growing yeast cells were more favorable to growth than dead or dormant ones.

2. *Bacteria.*—A small bacillus was used which had been isolated from a contaminated culture in which *Culex territans* had emerged. The medium, consisting of rotten algæ and water, was autoclaved in larger containers; two cultures in 500 cubic centimeter Erlenmeyer flasks and two in pint Mason jars. The reaction of the media in the four cultures was, pH 7.2, 8.6, 8.8, and 9.0. A few cubic centimeters of serum broth or of water of condensation from serum agar were added with the larvæ. Adults of *C. quinquefasciatus* emerged in all four cultures after 11 to 12 days at high room temperature. The mosquitoes were apparently normal; two females from one lot took blood when given the opportunity. Cultures were tested only microscopically after emergence, so that there is a possibility that some species of bacteria other than the one inoculated was present. Here one can be sure only of the fact that the mosquitoes were reared on bacteria alone.

3. *Infusoria.*—In connection with my work on *Anopheles* (1), I grew *Aëdes ægypti* to maturity on *Colpidium* alone. In the present series I obtained nearly full-grown larvæ of this species in a pure culture of *Colpidium;* but in no case did I obtain mature insects on uncontaminated cultures of infusoria. In one culture, consisting of green grass autoclaved with water and enriched by two cubic centimeters of serum broth, I obtained a large healthy adult of *A. ægypti* where the only contaminant proved to be a mold, probably a late invader and of little or no effect on the growth of the larvæ. *Colpidium* alone did not seem to be as good a pabulum for larvæ as when mixed with various bacteria. Larvæ of *C. quinquefasciatus* grew on *Colpidium* alone, and it is probable that this species as well as other culicines could have been brought to maturity on pure cultures had a sufficient number of trials been made.

4 *Algae*.—A nonmotile, unicellular, grass-green alga, *Scenedesmus*, was employed in all experiments. It grew luxuriantly on nearly all media. *C. quinquefasciatus* developed to maturity in a pure culture of this alga in a medium consisting of rain water plus about 5 per cent of serum broth Of 12 larvæ originally placed in this culture, only one, a small male, reached maturity. Although algæ were abundant and a favorable temperature was employed, emergence did not take place until 20 days after the hatching of the eggs. *A. ægypti*, fed on a pure culture of this alga, was also brought to maturity in a medium consisting of rain water plus serum broth. The single larva originally placed in the container, a large test tube, bred out in 16 days. In another culture a larva, bred in the same medium, emerged in 15 days. Algæ alone, even where an abundant growth was present, did not seem to be as good a pabulum for culicines as the colorless microorganisms.

Many adult culicines were obtained in various mixed and contaminated cultures Large specimens of *A. quinquefasciatus* developed in six days from the date of hatching on a mixture of infusoria and bacteria. In a culture of algæ contaminated with bacteria five out of six larvæ of *C. quinquefasciatus* originally placed in the culture reached maturity. The brackish water breeder, *A. sollicitans*, produced healthy adults in media containing 0 7 per cent NaCl and in those containing no more salt than that present in rotten-algæ cultures with or without the addition of earth. They were grown on algæ (one culture) and *Colpidium* (two cultures), in all cases contaminated with bacteria

Of the pure cultures tested, bacteria seemed to furnish the best pabulum, but a mixture of bacteria and infusoria, *Colpidium* or *Paramecium*, seemed to furnish the best medium of all This mixture, as well as the mixture of bacteria and algae, seemed to fulfill the main requirement—a continuous supply of actively growing microorganisms—better than any single food organism

The proportion of adults obtained from a given number of larvæ was greater among culicines than among *Anopheles*, and greater in *A ægypti* than in *C. quinquefasciatus*. Counting only cultures in which at least one adult emerged, I obtained 23 adult *C. quinquefasciatus* from 48 larvæ, and 8 adult *A. ægypti* from 9 larvæ originally sown Considerable variability was observed in the rate of development of larvæ of the same age and grown in the same medium.

Earth, sterilized with the media, was added to a number of cultures, but did not seem materially to promote the growth of larvæ, nor did it prevent the development to maturity of larvæ of *A. ægypti*, a species in nature rarely found breeding next to earth.

The success of cultures did not appear to depend on a close adjustment of the hydrogen-ion concentration. In a culture consisting of

rotten-algæ broth inoculated with bacteria, the hydrogen-ion concentration, originally pH 6.4, rose to 7.2 during the development of *C. quinquefasciatus* to maturity; in another it fell from pH 9.4 to 8.4. In a pure culture of algæ in rainwater plus serum broth, the pH at the time of the emergence of *C. quinquefasciatus* was 5.2. The alga was not in an active state of photosynthesis at the time the pH was determined. In other series in which *A. ægypti* were brought to maturity, the final pH varied from 6.6 to 8.2 in different cultures.

Nearly all cultures were kept at high room temperature, a temperature more favorable to culicines grown in these cultures than to Anopheles.

SUMMARY

Eggs of *Culex quinquefasciatus* and of *Aëdes ægypti* hatched readily in sterile nutrient media. Healthy adults of one or both of these species were obtained in pure cultures of yeast, of infusoria, of algæ, and of bacteria, and in various combinations of these microorganisms. In addition, adults of the *Culex territans* were obtained in cultures of mixed bacteria, and of *Aëdes sollicitans* in infusoria plus bacteria and in algæ plus bacteria. A combination of bacteria with infusoria or with algæ seemed to afford the best conditions for growth. No considerable growth of larvæ was obtained in sterile nutrient media or in cultures provided only with dead organic material.

PRINCIPAL CAUSES OF DEATH: 1926

The Department of Commerce announces that 1,285,927 deaths occurred in 1926 within the death registration area of continental United States, representing a death rate of 12.2 per 1,000 population, a slight increase over the rate for 1925.

This area in 1926 comprised 41 States, the District of Columbia, and 25 cities in nonregistration States, with a total estimated population on July 1, 1926, of 105,170,000, or 89.8 per cent of the estimated population of the United States.

The principal increases in death rates in 1926 were from diseases of the heart, from 186 to 199 per 100,000 population, influenza, from 30 to 41, pneumonia (all forms), from 94 to 103, measles from 2 to 8, and whooping cough, from 7 to 9.

Decreases in rates in 1926 were from diarrhea and enteritis, under 2 years, from 32 to 27 per 100,000 population, and typhoid and paratyphoid fever, from 8 to 7.

77453°—28——2

The following table shows for the death registration area in continental United States in 1925 and 1926 the number of deaths and the death rates per 100,000 population from leading causes:

Cause of death	Deaths in the registration area in continental United States			
	Number		Rate per 100,000 estimated population	
	1926	1925	1926	1925
All causes [1]	1,285,927	1,219,019	1,222.7	1,182.3

POLIOMYELITIS CASES REPORTED BY STATES, NOVEMBER 27 TO DECEMBER 24, 1927, AND CORRESPONDING WEEKS OF 1925 AND 1926

The following table is a continuation of the table appearing in the Public Health Reports December 9, 1927, page 3031. It gives the cases of poliomyelitis as reported by telegraph by State health officers for the four weeks ended December 24, 1927. Reports for the week ended December 31, 1927, will be found on page 27 of this issue of the PUBLIC HEALTH REPORTS.

Cases of poliomyelitis reported by State health officers November 27–December 24, 1927, compared with reports for the corresponding weeks of 1925 and 1926

State	Week ended—											
	Dec. 3, 1927	Dec. 4, 1926	Dec. 5, 1925	Dec. 10, 1927	Dec. 11, 1926	Dec. 12, 1925	Dec. 17, 1927	Dec. 18, 1926	Dec. 19, 1925	Dec. 24, 1927	Dec. 25, 1926	Dec. 26, 1925

PUBLIC HEALTH ENGINEERING ABSTRACTS

The Ventilation and Heating of Factories. II. M. Vernon and T. Bedford assisted by C. G. Warner. (*J. Indust. Hyg. 1927*, v. 9, 51–60.) From *Bulletin of Hygiene*, vol. 2, No. 7, July, 1927, pp. 539–540. (Abstract by P. S. Lelean.)

"The authors summarize usefully, for American publication, the results of their research for the British Industrial Fatigue Research Board (see Bulletin of Hygiene, v. 2, p. 180).

"1. Natural ventilation of large workrooms nearly always, especially in summer, needs to be aided by mechanical extraction of air; natural extraction amounts to only 10 per cent of that by fan, and may fall to zero or even be reversed. Heating by overhead steam pipes is condemned and application of heat beneath the floor is recommended.

"2. Mechanical ventilation, especially by the plenum (propulsion) system, is rapidly being generally adopted owing to its control facilities. Warmed air is forced into rooms through inlets of 5½ per cent floor area, the inlets being multiple, small, and low, so that the feet are warmed and the head kept relatively coo by the delivered warm air rising to escape by window exits at or above head levell of the workers.

"3. Practicable ideals may be thus tabulated:

	Summer (70° F.)	Winter (40° F.)
Cooling power of air (dry-katathermometer)	6	7
Air velocity (in feet per minute)	100	30
Air changes per hour	6	2

"Excess of temperature of air at head level over that at foot level less than 2° F.

"4. There is quoted the finding of the New York State Commission which investigated the conditions affecting the health of school children in America—'The avoidance of overheating is the primary essential,' and this dictum, which can not be too well known, is supported by observations showing that an increase of 7° over the optimum working temperature of 60° F. is associated with a 32 per cent increase in time lost by sickness among the workers."

Report of Bureau of Sanitary Engineering, Maryland State Department of Health, 1926. 19 pages. (Abstract by I. W. Mendelsohn.)

Air pollution.—(1) Hydrogen sulphide is being removed from coke-oven gases without odors; (2) at a reduction plant the drier gases are treated in a scrubber, all gases passing up through thin layers of excelsior while being sprayed with water; the gases are then dosed with liquid chlorine at the rate of 14 to 18 pounds per day; (3) an investigation was made into the effectiveness of treating all exhaust gases from a rendering plant after washing, 50 to 75 pounds of liquid chlorine per day being used; (4) carbon monoxide poisonings in a steel plant are under investigation.

New Water Filtration Plant at Wenatchee, Wash. Fred J. Sharkey and S. DeMoss. *Western Construction News*, vol. 2, No. 19, October 10, 1927, pp. 56–58. (Abstract by E. A. Reinke.)

A new 4 m. g. d. rapid sand gravity filter plant has recently been constructed as the first unit of a plan which provides for a normal capacity of 12 m. g. d. The intake in the Columbia River is constructed of reinforced concrete, 39 feet 6 inches long, 16 feet wide at the base, and 36 feet high. As the Columbia remains high only a few weeks in the year the gate control is housed in a compartment at the top and water allowed to flow over. The intake has inlets at several levels and serves as a sand trap. The sedimentation basin is 70 by 130 by 14 feet deep, divided into two equal compartments with a mixing chamber in each compartment equipped with motor-driven agitator. An interesting feature of this basin is that the roof slab was constructed to allow its use for a tennis court. The

filter and head house is built over the clear well, the first floor housing switchboard, meters, and high lift pumps; the second, offices, laboratory, dry feed machine room, and shops; the third providing chemical storage with a wash water tank 7½ feet deep above. Four 1 m. g. d. filter units are provided. Alum is used for coagulation. The cost totaled $221,500.

Recreational Use of Watersheds. C. G. Gillespie. *Western Construction News*, vol. 2, No. 19, October 10, 1927, pp. 59–60. (Abstract by E. A. Reinke.)

After reviewing recent events in New Jersey where resort owners and others succeeded in having a bill passed by the legislature legalizing swimming in all waters of New Jersey, the author presents an argument for promoting the reasonable attitude among waterworks men and recreational users of watersheds. He states that the self-interest of the recreationists will demand decent and reasonably clean conditions on watersheds and concludes with the following paragraph: "This widespread recreation development is a new problem upon water departments and upon public officials. It will be a mistake to let down the bars, however, as long as there are numbers who would become careless. On the other hand it is my opinion that the greatest good to all concerned will come from a gradual raising of the standards among the recreationists themselves. To such a program waterworks men can with profit undoubtedly lend their support."

New Orleans' New Filter Plant. Anon. *Public Works*, vol. 58, No. 10, October, 1927, pp. 398–399. (Abstract by W. J. Downer.)

Plant still under construction; one filter unit placed in operation about first of this year. New installation includes eighteen 4,000,000-gallon filters, equalization reservoir underneath filters, 2 grit, 2 lime mixing, and 4 coagulating basins, pumps and other necessary equipment. All structures rest on piles. Grit basins to be twice as long but same width as previous ones.

Baffles in coagulation basin are arranged to provide about twice the area on incoming side as on outgoing because past experience shows fully 90 per cent of suspended matter precipitates in first part of basin.

Most radical change in filters is new type of underdrain system. Advantages claimed are: It places construction entirely above bottom of filter, takes up small headroom, gives uniform distribution of wash water, costs considerably less than former type ($1,500 to $2,000 less per 4,000,000-gallon unit) and is expected to be less difficult to maintain. Bank sand of approximately 0.35 mm. effective size and 1.65 uniformity coefficient used.

The Relation of Endemic Goiter to the Iodine-Content of Soil and Drinking Water. R. McCarrison, C. Newcomb, B. Viswanath and R. V. Norris. *Indian Journal of Medical Research*, vol. 15, No. 1, July, 1927, pp. 207-246. (Abstract by L. M. Fisher.)

This study relates only to the classical type of endemic goiter described by the older writers as occurring in the Alps and other mountainous regions in association with cretinism, deaf-mutism and idiocy and which were studied by the authors in Himalayan India.

The distinctive epidemiological characters are: It has its home in high mountain ranges; prevails with different degrees of intensity in different parts of the same region and at different times; it has made its appearance in new places and disappeared from others; is especially prevalent in agricultural or pastoral districts, but is also rife in many towns; is commoner among the poor than the rich and especially among the agricultural laborers; has a seasonal endemicity, being higher in the spring; epidemics may occur among newcomers, such as school children and troops; there is a family predisposition; in regions of low endemicity it is commoner among females than males while in regions of high endemicity this disproportion disappears.

The freedom of localities in ex-Himalayan India is related to conditions other than the iodine content of their soils.

Drinking water containing 300 parts of iodine per 100,000,000,000 parts of water has not prevented endemic goiter in the presence of a high degree of bacteriological impurity in the water. Bacteriological impurity of a water supply combined with unhygienic conditions of life of the people is stated to be the essential cause of the disease. A deficiency of iodine favors its development.

Iodine-containing salt or substitutes therefore appear to prevent this type of endemic goiter, but under certain circumstances fails to do so.

Several methods of determining the iodine content of soils and water are given; also a bibliography.

Effluent Aerators Control Mechanical Filters. Malcolm Pirnie. *Engineering News-Record,* vol. 99, No. 10, September 8, 1927, pp. 376–380. (Abstract by C. G. Gillespie.)

The article describes the secondary aeration of filtered water ahead of the clear water basin at Providence, R. I., West Palm Beach, Fla., Poughkeepsie, N. Y., and Rahway, N. J. The available head between filters and clear well, variable according to the cleanliness of the filters, is utilized for aeration to reduce carbonic dioxide, taste, and odor. Amount of reduction of CO_2 as reported is 32 per cent, 41 per cent, 39 per cent, and 62 per cent in the several plants.

A controller adjusts the nozzle openings to maintain the filtered output. At Poughkeepsie the aeration is between the mechanical scrubbing filters and final slow sand filters. At Rahway the water is chlorinated ahead of the clear water reservoir and after contact with chlorine for several hours is aerated between the clear water reservoir and a high lift pump suction, taking advantage of the fact that the water level in the former basin is usually 10 feet above that in the latter. The aeration expels excess chlorine, and the water is now free of tastes and odors besides being less corrosive. Greater aeration efficiency would result from washing at a lower loss of head than customary. It remains to be seen how far it is reasonable to go to secure the secondary aeration and the additional CO_2 and odor removal.

Malaria in the Philippines. Walter V. D. Tiedeman. *Journal of Preventive Medicine,* vol. 1, No. 3, 1927, pp. 205–254. Translation of an abstract by Martini in *Zentralbl. fur die Gesamte Hygiene,* vol. 15, August 25, 1927, p. 654.

In the Provinces of Laguna and Pampanga, endemic malaria occurs in moderation and is generally more prevalent in the vicinity of the rivers, in the foothills, and along the borders of uncultivated lands. There are seasonal variations in the occurrence of malaria, attributable to the dry seasons during which river-breeding types such as *Anopheles ludlowi* and *minimus* predominate. To what extent the apparent relapses of cases are classed as new infections can not be stated; the possibility often exists. On the other hand, the treatment is frequently insufficient. The death rate is not excessive. The deaths credited to malaria are too great, since frequently other causes of death are reported as due to malaria. Nevertheless malaria is of serious consequence. *Anopheles barbirostris, fuliginosus, sinenis, kochi, ludlowii, maculatus, philippinensis, tessellatus, subpictus,* were found, but no tree-hole breeders. On farm lands, irrigation and drainage ditches were the only breeding places. Most species propagate without interruption. Only *ludlowii* and *minimus* show seasonal fluctuation as river breeders. The rice-field types such as *A. sinensis* are mostly harmless. The people are readily accessible to the Anopheles because of the type of their houses, and carriers are widely distributed. Quinine prophylaxis is only possible under military discipline. However, much can be accomplished for the thickly settled regions with Paris green and intelligent use of the irrigation ditches and at relatively low cost. For the thinner populated areas, where the malaria rate is lowest, these methods of control are too expensive.

The Control of Malaria in Malaya. Regular London Correspondent, *Journal American Medical Assn.*, vol. 89, No. 7, August 13, 1927, p. 534. (Abstract by C. H. Kibbey.)

The Malayan campaign against malarial fever was almost the first begun, and has been the most persistent, the widest, and the most successful of malaria-control campaigns in British areas –perhaps in the world. Selangor, a town of 3,576 inhabitants, is contained in an area of 290 acres, of which 22 acres were swamp and 85 jungle or dense growth. The annual fever death rate stood at 300 per thousand inhabitants, as against the English death rate of 11 or 12. The swamp was drained and the work of mosquito control was begun. This work from 1901 to 1905 cost about $20,000, and during the same period $30,000 was spent on malaria control at the neighboring town of Port Swettenham. The work of malaria prevention in Malaya has progressed until to-day it has become a part of the life of the whole community. The result is that the death rate of Singapore has fallen since 1911 by nearly a half. The whole population of Malaya has learned the value of the campaign against malaria and has become united in supporting that campaign. Laws have been passed imposing on every one the duty of taking preventive measures in the home. It has become a crime to neglect such precautions as the emptying of vessels containing water and the drainage of puddles or other breeding places of mosquitoes.

Measures of Outstanding Importance in the Prevention and Control of Malaria. M. A. Stuart. *U. S. Naval Bulletin*, vol. 25, No. 4, October, 1927, pp. 996–1010. (Abstract by H. E. Hargis.)

The occasion for the writing of this paper was the quartering in Olongapo of 450 marines, nearly all of whom had malaria in about six weeks. The methods of prevention and control are listed as: (1) Elimination of breeding places by filling in and drainage; (2) destruction of larvae through oiling, larvicides, and the use of *Gambusia affinis;* (3) destruction of adult mosquitoes by fumigation and capture; (4) protection of persons from mosquitoes by screening and bed nets; (5) segregation of nonimmunes from unprotected native villages; (6) medicinal prophylaxis by the routine use of quinine. Authorities are quoted on the application of these measures and each measure is taken up in detail.

The Possibilities of Paris Green as An Anopheles Larvicide. B. S. Chalam. *Indian Journal of Medical Research*, vol. 14, No. 4, April, 1927, pp. 867–873. (Abstract by L. M. Fisher.)

Paris green—aceto-arsenite of copper—is also known in Europe as Schweinfurt green. In the experiments carried out by American workers no attempts were made to remove vegetation.

Before applying the Paris green, larvae averaged 11.1 per dip. Afterwards they averaged 0.5 larvae per dip and the surviving larvae were very small. Fifteen grains to 10 square yards of water surface are deemed sufficient unless in very dense vegetation. The material was applied with unskilled labor either by hand or using a hand bellows.

The Resistance of Anopheles Eggs to Desiccation. B. S. Chalam. *Indian Journal of Medical Research*, vol. 14, No. 4, April, 1927, pp. 863–866. (Abstract by L. M. Fisher.)

Eggs of *A. subpictus* and *A. stephensi* were found to be viable after desiccation up to a period of 12 days. They hatched normally and some grew to maturity.

(Abstractor's note: This study was apparently suggested by Mayne's paper, "Notes on the influence of temperature and humidity on oviposition and early life of Anopheles," Public Health Reports, vol. 41, part 1, 1926, p. 986. Mayne found that the eggs of *A. quadrimaculatus* were viable after periods of desiccation up to 16 days, and *A. crucians* after periods of desiccation up to 21 days.)

DEATHS DURING WEEK ENDED DECEMBER 24, 1927

Summary of information received by telegraph from industrial insurance companies for the week ended December 24, 1927, and corresponding week of 1926. (From the Weekly Health Index, December 29, 1927, issued by the Bureau of the Census, Department of Commerce)

	Week ended Dec. 24, 1927	Corresponding week, 1926
Policies in force	69, 620, 546	66, 348, 549
Number of death claims	12, 481	11, 629
Death claims per 1,000 policies in force, annual rate	9. 3	9. 1

Deaths from all causes in certain large cities of the United States during the week ended December 24, 1927, infant mortality, annual death rate, and comparison with corresponding week of 1926. (From the Weekly Health Index, December 29, 1927, issued by the Bureau of the Census, Department of Commerce)

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 99 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 30,600,000. The estimated population of the 93 cities reporting deaths is more than 29,950,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended December 17, 1927, and December 18, 1926

	1927	1926	Estimated expectancy
Cases reported			
Diphtheria:			
43 States	2,277	2,056	
99 cities	1,212	1,091	1,210
Measles:			
41 States	4,817	6,006	
99 cities	1,437	1,129	
Poliomyelitis:			
43 States	114	20	
Scarlet fever:			
43 States	3,616	4,185	
99 cities	1,245	1,614	1,131
Smallpox:			
43 States	799	682	
99 cities	112	92	62
Typhoid fever:			
43 States	339	372	
99 cities	45	68	59
Deaths reported			
Influenza and pneumonia:			
93 cities	763	858	
Smallpox:			
93 cities	0	1	
Charleston, W. Va	0	1	

City reports for week ended December 17, 1927

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1918 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population July 1, 1925, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended December 3, 1927.—The following report for the week ended December 3, 1927, was transmitted by the Eastern Bureau of the Health Section of the Secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

Egypt.—Alexandria.
India.—Rangoon.
Dutch East Indies.—Makassar, Cheribon.

CHOLERA

India.—Calcutta, Rangoon.
Straits Settlements.—Singapore.
Dutch East Indies.—Batavia.
Siam.—Bangkok
China.—Canton.

SMALLPOX

Aden Protectorate.—Aden.
Iraq.—Basra.
India.—Bombay, Cochin, Calcutta, Madras, Rangoon.
Dutch East Indies.—Surabaya.
Siam.—Bangkok.
Kwantung.—Dairen.
Manchuria.—Mukden, Changchun.
Japan.—Osaka.

Returns for the week ended December 3 were not received from Banjermasin, Dutch East Indies, or Vladivostok, Union of Socialist Soviet Republics.

CANADA

Communicable diseases—Quebec—Week ended December 17, 1927.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended December 17, 1927, as follows:

Disease	Cases	Disease	Cases
Chicken pox	64	Scarlet fever	97
Diphtheria	98	Smallpox	12
German measles	4	Tuberculosis	24
Influenza	5	Typhoid fever	18
Measles	129	Whooping cough	13

ECUADOR

Plague—Plague rats—Guayaquil—November, 1927.—During the month of November, 1927, nine cases of plague with three deaths were reported at Guayaquil, Ecuador.

During the same period, of 23,240 rats trapped, six rats were found plague infected.

EGYPT

Further relative to plague—Alexandria—November 25–December 1, 1927.—On November 25 and 26, 1927, two additional cases of plague, both bubonic, were reported at Alexandria, occurring in the group of Barbary workmen in which the two previously reported cases occurred,[1] November 22 and 23, 1927. On December 1, two cases were reported in a group related to that in which the two previously reported cases occurred. Both of these last-named cases were found dead in their houses. The houses were stated to be situated about 1 kilometer from the port.

ESTONIA

Communicable diseases—October, 1927.—During the month of October, 1927, communicable diseases were reported in the Republic of Estonia as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	1	Scarlet fever	237
Diphtheria	37	Tuberculosis	125
Measles	19	Typhoid fever	72

Population, 1,107,059

IRISH FREE STATE (IRELAND)

Typhus fever—County Cork—December 4–10, 1927.—During the week ended December 10, 1927, three cases of typhus fever were reported in the urban district of Cork County Borough.

PUBLIC HEALTH REPORTS

ISSUED WEEKLY

BY THE UNITED STATES
PUBLIC HEALTH SERVICE

VOLUME 43 :: :: NUMBER 2

JANUARY 13 - - 1928

SPECIAL ARTICLES

Typhoid Fever in the United States
Mortality Among American Negroes
Scarlet Fever: Prevention and Control
Reports of the Health Section, League of Nations

UNITED STATES
GOVERNMENT PRINTING OFFICE
WASHINGTON
1928

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

Asst. Surg. Gen. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

PUBLIC HEALTH REPORTS

VOL. 43 JANUARY 13, 1928 NO. 2

PREVALENCE OF TYPHOID FEVER IN THE UNITED STATES

Preliminary reports from the health officers of 36 States for 50 weeks of 1927 show that the incidence of typhoid fever during 1927 was less than it was during the preceding two years. For 50 weeks in 1925 these States reported 30,700 cases of typhoid fever; in 1926, 25,600 cases; and in 1927 only 22,400 cases. The aggregate population of the 36 States is about 88,000,000.

The following table gives a comparison of the reports of cases of typhoid fever from these States for the 16 weeks from August 28 to December 17, 1927, with the reports for the corresponding period of the years 1925 and 1926.

Four weeks ended	1927	Corresponding weeks	
		1926	1925
Sept. 24, 1927	3,533	4,577	1,456
Oct. 22, 1927	2,680	4,045	3,805
Nov. 19, 1927	1,916	2,607	2,703
Dec. 17, 1927	1,218	1,479	1,928
Total	9,347	12,708	12,892

The typhoid fever case and death rates for 1925 were higher than the rates for the years from 1922 to 1924, inclusive, although the 1925 rates were lower than any ever recorded before 1920.

The typhoid fever death rate in the registration area of the United States dropped from 35.9 per 100,000 population in 1900 to 6.5 in 1926.

MORTALITY AMONG NEGROES IN THE UNITED STATES

At the request of Negro sanitarians for facts concerning mortality among American Negroes, Public Health Bulletin No. 174 has been prepared in the Office of Statistical Investigations with the idea of summarizing the data published annually by the Bureau of the

Census in order to make it available for persons working in the field of public health among Negroes. The bulletin is intended as a handbook and not as a study of any particular phase of Negro mortality.

Comparisons are made between colored and white mortality among populations of the same limited area, i. e., the Southern States of the death registration area, those States being selected as including the bulk of the Negro population and representing the Negro race in what might be considered its more nearly normal environment. For some purposes data for more Northern States have been presented.

Following is a brief outline of the data presented in the bulletin:

(1) The distribution and increase of the Negro population in the United States.

(2) Birth rate by States (1920) based on the female population 15–44 years of age.

(3) Mortality from all causes, specific for color, age, urban and rural areas of separate States, 1920.

(4) Mortality from important causes by color and at different ages, including such causes as pulmonary tuberculosis, pneumonia, organic heart, acute nephritis and Bright's disease, cancer, diphtheria, whooping cough, measles, and scarlet fever. These rates are based on the records for the Southern States of the death registration area and are for the year 1920.

(5) The trend of mortality from all causes for three southern cities, Baltimore, Charleston, and New Orleans, from approximately 1870 to 1923. The trend of important causes or groups of causes such as pulmonary tuberculosis, acute pulmonic diseases, cardio-renal diseases, cancer, diphtheria, whooping cough, scarlet fever, and measles is presented for the white and colored populations of New Orleans, from 1884 to 1921.

(6) Infant mortality by color and by separate cause for the birth-registration area of 1920.

Attention has been called to those diseases, such as tuberculosis and malaria, which are relatively more of a menace to the Negro race than to the white at the present time, and which offer a wide field to those in public-health work who are interested in furthering a knowledge of preventive measures against these diseases in the Negro race.

[Public Health Bulletin No. 174, containing this information regarding Negro mortality, may be purchased from the Superintendent of Documents, Government Printing Office, Washington, D. C., at 15 cents per copy.]

SCARLET FEVER: ITS PREVENTION AND CONTROL

A revision of Supplement No. 21 to the Public Health Reports, issued November 27, 1914. The original article was prepared by Surg. J. W. SCHERESCHEWSKY. Revised, December, 1927, by Surg. R. E. DYER, *United States Public Health Service.*

Scarlet fever is regarded, by the informed, as one of the dreaded diseases of childhood, not only because an attack may be so malignant as to cause death in a short time, but also because of the many and grave complications with which it may be attended, and because the hope of recovery, even in cases apparently mild at the outset, has proved too often illusory.

This pamphlet is addressed to the general public, whose intelligent cooperation is necessary in all preventive measures against diseases, in the hope that it will aid, in some small degree, in spreading that knowledge of communicable diseases which should be in the possession of every citizen to enable him to do his share in their prevention.

Occurrence of scarlet fever.—Scarlet fever is more especially a disease of temperate climes, practically always being present in the large cities. In the United States it affects particularly the Northern States, being more prevalent there than in the South.

Scarlet fever and season.—Scarlet fever prevails during the colder months of the year. With the opening of the schools, the autumn months are always signalized by the marked increase in the number of cases of scarlet fever reported to health officers, each month showing a progressive increase until a maximum is reached in December and January. Only a small decline in the number of reported cases is shown in the spring months, but in July and August there is a great falling off, the number of cases reported being very much less than in the winter months.

Age and scarlet fever.—While scarlet fever may attack persons of any age, not even the very old being exempt, it is primarily a disease of infancy and childhood. The susceptibility to the disease becomes rapidly less with increasing years. From the figures for 1924, published by the Bureau of the Census, 44 per cent of the total deaths from scarlet fever in the registration area of the United States took place in children less than 5 years old, 70 per cent in children less than 10, 79 per cent in children less than 15, and 89 per cent in persons less than 25 years of age.

On the other hand, very young infants do not seem very susceptible to contracting scarlet fever. The disease is seldom seen in infants less than 7 months old. The disease, however, is very fatal to infants if they are attacked. The greatest susceptibility to scarlet fever falls between the second and the ninth year, over 66 per cent of the deaths from scarlet fever taking place in this age period.

The fatality of scarlet fever.—The virulence of scarlet fever is variable. In epidemics the percentage of those stricken by the disease who die varies from 1 to 15.

Age is an important factor, the rule being that the younger the patient the more fatal the disease.

The cause of scarlet fever.—For many years it has been known that certain germs called hemolytic streptococci are commonly present in the throats of acute cases of scarlet fever. Evidence was gradually accumulated through the painstaking researches of scientists throughout the world to show that these hemolytic streptococci might have a direct relationship to scarlet fever, culminating finally in the work of Drs. George F. and Gladys H. Dick, of Chicago. These two scientists succeeded in producing clinical scarlet fever in volunteers by using cultures of hemolytic streptococci which had been isolated from cases of the disease. As a result of this work, scarlet fever is now generally regarded as being caused by a hemolytic streptococcus. These germs are found in the throats of cases of scarlet fever and from them are transferred to the throats or nasal passages of other persons, where they multiply. These germs attack the mucous membranes lining the upper air passages, the earliest noticeable result being a reddening and soreness of the throat. As these organisms grow they produce a toxin (poison) which is absorbed by the body and causes the fever, rash, and toxæmia or symptoms of poisoning.

The symptoms of scarlet fever.—Some description of the symptoms of scarlet fever is desirable so that all may be on their guard against the disease. Its principal symptoms consist of sore throat, fever, rapid pulse, the breaking out of a bright-red rash (from which it takes its name) over the body and extremities, and usually swelling and tenderness of the glands of the neck. These symptoms are followed by a stage known as the period of desquamation, or peeling, during which the outer layers of the skin are shed in scales, flakes, or patches.

We can distinguish three well-marked stages in the course of an attack of scarlet fever:

1. The period of invasion.
2. The period of eruption.
3. The period of desquamation.

Period of invasion.—The disease strikes suddenly. A child, hitherto apparently in the best health, is seized with sore throat and fever, very often with vomiting, and, in infants, convulsions. The fever mounts rapidly, the skin feels unusually hot and dry to the touch, the tongue is furred, the throat parched, the face flushed and somewhat bloated. Cough and running of the nose are unusual. This stage usually lasts 24 to 36 hours.

Stage of eruption.—The rash usually appears on the second day, but may be deferred for 48 hours. On the other hand, it may begin to come out a few hours after the first symptoms. It appears first on the neck and chest as a breaking out of fine, scattered, bright points implanted on a scarlet flush. It spreads rapidly, so that by the evening of the second day the entire body may be covered. The eruption at its height has a vivid scarlet hue and is more marked on the inner surfaces of the arms and legs and where joints make folds of the skin, as in the groins and at the elbows.

In some cases the rash is patchy instead of uniform, with islands of normal skin. At other times tiny elevated patches appear, as in measles, but this is not so common as in measles.

In malignant attacks bleeding may take place in the skin, causing large purplish patches.

After persisting at its height for two or three days, the rash gradually fades, the fading being accompanied by a progressive fall of the fever.

Period of desquamation or peeling.—With the fading of the eruption and the fall of the fever the skin looks stained and feels rough. Gradually its outer layers begin to be thrown off, the process usually beginning about the neck and chest. The amount of peeling usually bears some relation to the previous intensity of the rash. When this has been vivid and its duration prolonged, large flakes and patches come away. Rarely the nails and hair are shed. On the other hand, with mild eruptions the peeling may be much less marked, consisting of branlike particles only. The entire pr ess lasts 10 to 20 days.

Throat symptoms.—Inflammation of the throat is a prominent symptom in scarlet fever. This is present in various grades and may vary from redness of the hard palate and inner surface of the cheeks, with some swelling and more vivid redness of the soft palate and tonsils, to the condition known as "diphtheroid," with much increased swelling and inflammation of the tonsils and neighboring parts, with extensive formation of a membrane over the tonsils and soft palate.

In these severe cases extensive membrane formation in the throat may lead to death of the underlying tissues, so that large sloughs form. The swelling of the glands and soft parts of the neck may be so extensive that breathing is interfered with and death ensues from suffocation, or deep abscesses form, endangering life and markedly prolonging convalescence.

The tongue in scarlet fever.—The tongue in scarlet fever has a characteristic appearance. At the outset of the disease it is coated with white, the edges being red. The little papillæ or prominences with which the tongue is studded emerge through the white coating and can be seen as little red points dotting the white surface.

Somewhat later in the disease the white coating disappears, leaving the tongue rough and red, often glazed. The papillæ remain considerably swollen, and this, together with the beefy appearance of the tongue, constitutes a condition characteristic of scarlet fever, which the writers describe as the "raspberry tongue."

Types of scarlet fever.—Scarlet fever shows marked variations in its severity. There are mild or abortive cases in which the rash is scarcely visible, or in which the sore throat and the "raspberry tongue" may be the only signs of the disease. In certain epidemics, particularly in schools, this type of the disease may constitute over a third of the cases.

On the other hand, the symptoms may be so severe that the patient, overwhelmed by the poison of the disease, may die within 24 to 36 hours, with high fever, great restlessness, delirium, and convulsions.

In other cases the throat symptoms are prominent and may be of the utmost severity. Rapid and thick membrane formation takes place which may extend into the interior of the nose, and into the ears through the Eustachian canals (openings of the ear into the throat). Death may ensue from suffocation, due to the swelling of the soft parts, or gangrene may set in, causing a fatal issue. Convalescence may be much delayed by persistent enlargement of the neck glands and the formation of deep abscesses in the neck, or by purulent discharges from the nose.

The complications of scarlet fever.—Scarlet fever is distinguished by the variety and severity of its complications, which may develop in cases apparently mild at the outset. The most common of these are inflammation of the kidneys (nephritis), ear complications (middle-ear disease), inflammation of the lining membrane of the heart (endocarditis), inflammation of lymph glands (adenitis), and joint affections. Of these, nephritis and ear complications are by far the most common.

Inflammation of the kidneys (nephritis).—Inflammation of the kidneys may develop, usually in the second or third week of the disease, even in the mildest cases. The symptoms vary greatly in severity from instances in which the condition is shown only by the presence of albumen in the urine, pallor, and slight swelling of the eyelids and feet, to those of greater severity with scanty urine loaded with albumen and general swelling of the body, or to the severe and rapidly fatal cases with scanty, bloody urine or urine completely suppressed, with vomiting, convulsions, and loss of consciousness.

There is evidence to the effect that an attack of scarlatinal nephritis, even if apparently recovered from, may predispose the individual later in life to develop chronic kidney disease.

Ear complications.—These are very common. They are caused by an extension of the throat inflammation to the interior of the ears through the canals by which they open into the throat. The inflammation may extend to the bony cells of the temporal bone behind the ear, causing mastoid disease; the hearing may be destroyed, or the inflammation may extend to the brain, causing dangerous brain complications. The ear complications of scarlet fever are a common cause of deafness.

Infectiousness of scarlet fever.—It is indeed fortunate that scarlet fever does not show the very ready communicability of measles or whooping cough. Rather intimate contact with the sick seems to be required to transmit the disease. Observations have been made which allow us to estimate roughly the frequency with which persons, after exposure, contract the disease. These show that about 30 per cent of children sicken with scarlet fever after exposure, while in the case of measles about 99 per cent of those unprotected by a previous attack will take the disease under like conditions.

Period of incubation of scarlet fever.—While the average period of incubation of scarlet fever (i. e., the period between exposure and the appearance of symptoms) has been stated to be from 2 to 4 days, probably with a maximum of 7, a few examples of what seem to be longer periods are recorded.

Portal of entry of the scarlet-fever germ.—All the evidence tends to show that the mouth is the usual gateway through which the germ of scarlet fever enters the body.

How scarlet fever is "caught."—Each new case of scarlet fever is derived from some previous case of the disease. The scarlet fever germ is present in the discharges from the mouth, nose, and throat of the sick. When there is a discharge from the ears, as a result of ear complications, this discharge also may be infectious. This is true of other pus discharges, as from abscesses. The urine, too, in cases of scarlatinal nephritis, and matter vomited at the onset or during the course of the disease, may contain the infecting agent of scarlet fever.

The disease is transmitted from those sick with scarlet fever to the well who come in contact with them because these discharges get on the hands or mucous membranes of such persons. The infection is caused by direct contact, as by kissing, or by being sprayed with the infected nose and throat discharges, in the act of coughing, sneezing, or talking (droplet infection), or indirectly through various objects, such as drinking cups, candy, apples, pencils, pocket-handkerchiefs, towels, and the like which have been placed in the mouth or infected with the discharges of those sick with scarlet fever.

It has often been pointed out that the chief factor in the spread of such diseases as scarlet fever and diphtheria is the freedom with

which the fluids of the mouth are exchanged among human beings, especially among children. But little observation is needed to convince us of the frequency, during the day, with which the hands are carried to the mouth and then handle objects in common use. This tendency is, of course, greatest among children.

Duration of the communicability of scarlet fever.—Scarlet fever can be transmitted from the time of onset until the infectious agent is no longer present in the mucous membranes of the nose and throat nor in unnatural discharges, as from a running ear which has appeared as a complication in an attack of the disease.

On account of the difficulty of definitely identifying the germ of scarlet fever it has thus far not proved feasible to determine the duration of communicability of scarlet fever by throat culture, as is done in the case of diphtheria. In the majority of instances it is probable that uncomplicated cases of scarlet fever are no longer infectious in the fourth week of the attack.

Scarlet fever "carriers."—The spread of a number of communicable diseases is assisted by the agency of "carriers," i. e., apparently well persons who harbor in their bodies and spread the germs of a particular disease. The agency of "carriers" is important in disseminating such diseases as diphtheria, typhoid fever, cerebrospinal meningitis, cholera, and scarlet fever.

These carriers consist of the "missed cases," viz, those persons who have suffered from scarlatinal sore throat alone, without a recognized eruption; who have not been sick enough to go to bed or, possibly, even complain of their symptoms, and the convalescent "carrier," the child, who after an attack is allowed to mingle with his playmates too soon, or who continues to harbor the contagion in his nose and throat for a long time after apparent recovery. Such persons undoubtedly play an important part in spreading scarlet fever.

Milk-borne scarlet fever.—There are numerous records of outbreaks of scarlet fever in which the infection was conveyed by milk. These outbreaks were usually of an explosive character, an unusual proportion of adults were attacked, and the disease was often severe. In every instance the source of the infection was shown to be due to the presence of persons suffering from scarlet fever, either on the dairy farm or among the persons engaged in handling the milk.

Immunity to subsequent attacks of scarlet fever.—The protection against future attacks conferred by a single attack of scarlet fever usually seems strong and lasting, although second and even third attacks of the disease have been observed. Relapses also are occasionally noted, i. e., a child, apparently well upon the road to recovery, sickens anew and goes through a second siege of the disease with all its attendant symtoms, including peeling.

Complication with other infectious diseases.—It must not be supposed that, because a person is suffering from scarlet fever he is thereby protected from having other communicable diseases at the same time. Scarlet fever has frequently been observed to be complicated with measles or diphtheria.

Prevention of scarlet fever.—It is plain, from what has been said, that scarlet fever is no disease to be lightly held To infants and young children it is a very fatal affection. Yet, in spite of its communicability, it is by no means a disease which "every child is bound to have sooner or later." The folly of the complacent attitude which permits the exposure of children to the diseases of childhood "so that they may have them over and done with" can not be too strongly condemned. If we succeed in protecting our children from scarlet fever during childhood, the chances that they will suffer from the disease later will be very greatly reduced. By so doing we will have protected them from what constitutes a very real menace to their lives, or to their subsequent physical efficiency.

Within recent years the Doctors Dick of Chicago have developed a test to determine susceptibility to scarlet fever. This test is called the Dick test and is similar to the Schick test for determining susceptibility to diphtheria It consists in injecting a minute amount of the scarlet fever streptococcus toxin or poison into the skin (usually of the forearm). If the child is susceptible, a red area about the size of a dime, or larger, will appear at the site of injection in about 24 hours.

The scarlet fever streptococcus toxin is made by growing the hemolytic streptococci of scarlet fever in broth for a few days. The germs are then carefully filtered out, while the toxin, being soluble, remains in the broth.

In addition to using this toxin to test susceptibility to scarlet fever, larger amounts of the same toxin may be given to susceptible individuals to render them insusceptible. When this ability to resist the toxin is developed by injecting the toxin, it appears within a few weeks. At present five doses are given to susceptible persons, at weekly intervals.

This method of immunization is especially useful in institutions, and in the protection of nurses who are about to undertake duty in the care of cases of scarlet fever.

Diagnosis of scarlet fever.—While the responsibility for the diagnosis of scarlet fever must rest upon the attending physician, the citizen can be of material assistance in limiting the spread of scarlet fever by being constantly alive to the possibility of outbreaks of the disease in his family. If a child be suddenly taken with vomiting, and fever, or with dryness, tickling, or soreness of the throat, if soreness of the throat alone be complained of, or if any rash be dis-

covered on the body in absence of other symptoms, no time should be lost in isolating the child and calling in a physician in order to ascertain the nature of the disorder as promptly as possible. It is the mingling of children sickening with a communicable disease with other children before its nature has been determined which helps to spread such diseases.

A great deal could be accomplished in the way of controlling the communicable diseases of childhood if it were the invariable rule in every household to isolate all children from other children as soon as they become ill until the nature of the sickness has been made out, especially when such illness is accompanied by sore throat, running nose, or huskiness of the voice.

The care of scarlet fever in the home.—The important principle to remember, in the care of scarlet fever, is that a child sick with scarlet fever who is carefully isolated does not transmit the disease.

The sick room.—The first rule, therefore, in the care of scarlet fever is to place the patient at once in a separate room. This room, if possible, should be on the story of the house the least in use, its adaptability for sick-room purposes being considered. The furniture left should be reduced to strict necessity and be of a kind readily cleansed.

There should be no such fancied attempts at purifying the air as by hanging up sheets wet with disinfectants. Such measures are not only useless but tend to give a false sense of security.

Separate linen, bedclothes, etc.—The patient should be provided with separate bedclothing, nightgowns, towels, eating utensils, and drinking vessels for his exclusive use. These should be kept rigidly separate from those used by the rest of the family. After use they are to be soaked for an hour or two in one of the disinfectant solutions given below, or better, boiled in soapsuds.

Attendant for the patient.—The patient should be provided with an attendant who remains with him and holds no communication with the other members of the family. This attendant should be the only person coming in contact with the patient apart from the attending physician.

Use of disinfectants.—The best method of disinfecting articles used by patients is by boiling. Discharges from nose and throat of patients may be received into pieces of cotton gauze or old, clean squares of linen, which should be burned immediately after use. In case it is found impracticable to practise the above procedure, a tub of good disinfectant solution should be provided for soaking articles used by the patient. The following are proper disinfectant solutions:

1. Two per cent solution of phenol (carbolic acid.)
2. Two per cent solution of liquor cresolis compositus, U. S. P. (compound solution of cresol).

A 2 per cent solution is made by adding 3 ounces (6 tablespoonfuls) of disinfectant to 1 gallon of water. Surfaces soiled with discharges from scarlet-fever patients should at once be flooded with the disinfecting solution. Partially eaten food should also be disposed of by burning. Dishes used by the patient should be boiled before being removed from the sick room.

Care of the patient during peeling.—During desquamation the process is facilitated by rubbing the body with some bland unguent like olive oil or cocoa butter.

Care of the attendant's hands.—It is important to remember that the hands become readily infected when caring for scarlet fever patients. Unnecessary handling of the patient, therefore, should be avoided. Whenever contact is necessary the hands should be cleansed in hot soapsuds.

Other precautions for the attendant.—A loose gown or wrapper and a head covering should be provided for the protection of the attendant's hair and clothing. These coverings should always be regarded as infected, and not sent out of the room until they have been boiled or soaked in disinfectant for an hour. The attendant should wear dresses of material not injured by disinfecting, as these should also be disinfected. Gowns and head coverings should also be provided for the attending physician. These are kept outside the room.

Ventilating and cleansing the room.—There is little tendency to "catch cold" in scarlet fever. The bedclothes should be light and the room aired thoroughly several times a day and well ventilated at all times. No sweeping should be done, but the floor and furniture wiped with cloths dampened in disinfectant solution instead. After use the cloths should be soaked in disinfectant solution.

Subsequent cleansing and disinfection of the sick room.—The cleansing and disinfection of the sick room after recovery from scarlet fever will, in cities, be governed by the regulations of the local health office; but cleansing and airing of the sick room should always be done. When the householder must follow his own initiative in the matter, his reliance should be placed upon thorough cleansing of the room with soap and water, and upon the action of fresh air and sunlight. Gaseous disinfection is not only probably useless but creates a false sense of security.

Treatment of children who have been exposed to infection.—When a case of scarlet fever occurs in a family, the other children have probably been exposed to infection. As has been previously stated, there is a good chance, though exposed, of their escaping the disease especially if isolation of the sick has been prompt and thorough. It is therefore advisable to send such children away at once to friends or relatives not having small children of their own. While there they

should be carefully observed for symptoms of commencing scarlet fever until the incubation period has passed. If they are school children, they should be kept away from school during this time. The adult members of the family, however, who are not sick, may come and go, provided the house is so arranged that they do not come in contact with the patient. They should wash the hands and face carefully before leaving the house.

As the protection following the immunizing injections of scarlet fever streptococcus toxin develops rapidly, many contacts may be protected in this manner. Before beginning the immunization of exposed persons they should be given the Dick test to determine susceptibility. At the time the test is performed, throat and nose cultures should also be made to determine the presence or absence of hemolytic streptococci. If by the test the child is shown to be susceptible and shows no signs of oncoming scarlet fever, such as slight elevation of temperature or sore throat, the first immunizing dose may be given at once. An exposed child who, in addition to having a positive Dick test also harbors the germs in the nose and throat, should be examined carefully each day for signs of developing the disease, and no further injections of toxin gi n as long as such symptoms persist.

Exposed children who are positive to the Dick test and who show symptoms of oncoming scarlet fever may be given an early therapeutic dose of scarlet fever streptococcus antitoxin.

Reporting the case.—An important step in the control of any communicable disease lies in the knowledge of its prevalence by the sanitary authorities. It is a public duty to report cases of scarlet fever.

It is likewise the householder's duty to observe scrupulously all regulations made by local health authorities in regard to the quarantine of scarlet fever cases.

Other precautions to be observed.—As scarlet fever is capable of transmission through milk, it is important that a vessel be placed outside the house, as on the porch, into which the milkman may empty the milk. This will prevent the bottles from becoming infected in the house. Milk bottles once admitted to the house should not be returned to the milkman before they are thoroughly disinfected by complete immersion in water, actually boiling. In no case should any member of the family coming in contact with the sick handle the bottles.

When a household in which there is a case of scarlet fever is engaged in any occupation having to do with the handling or distribution of food, such as the grocery business, dairying, the making of ice cream, and the like, such business should be discontinued as long as the case of scarlet fever remains on the premises, or until the patient has been

removed to a contagious-disease hospital, and other members of the family observed for a sufficient length of time to assume their escape from the infection.

The public control of scarlet fever.— It is evident from the foregoing that the proper care of scarlet fever in the home is no easy problem even in the most intelligent and well-to-do families. Thorough isolation of the sick in the tenement districts of cities is well nigh impossible.

Under such conditions the control of the spread of scarlet fever must be in the hands of the local sanitary authorities. The most important equipments to this end are: First, adequate contagious-disease hospitals to which those suffering from scarlet fever may be removed, when it is clear, from an inspection of the premises, that cases of scarlet fever can not remain at home without danger of spreading the disease; second, an efficient corps of inspectors and nurses for the visiting and sanitary control of the cases of scarlet fever reported; and, third, an adequate system for the medical supervision of school children, so that cases of scarlet fever shall be early detected and the proper precautions taken before the infection has had a chance to spread among the pupils. Teachers also can aid greatly in the control of scarlet fever by being familiar with the symptoms attending its onset, encouraging their pupils to let them know whenever they feel sick, removing at once from the classroom any child having sore throat or seized with sudden vomiting, and reporting their action at once to the proper authorities. The school nurse and the school physician are indispensable agents in limiting the spread of scarlet fever in the schools.

School authorities will materially contribute their share by abolishing in schools the common drinking cup, the common towel, the common lead pencil, which, though slowly vanishing, are still too frequently encountered in our schools.

Immunization of susceptible persons by use of injections of toxin may be used especially where the chances of exposure are apt to be great. The immunizing toxin has been used too short a time to warrant a statement as to the permanence of the immunity so produced.

In case of death from scarlet fever, public funerals should not be allowed, because when many persons gather in and about a house in which disease has occurred there is great danger that some one may catch it. The danger is not from the dead body, if properly prepared, but from members of the afflicted household, some of whom may be carrying the germs in the throat and nose, and may even be on the verge of coming down with the disease.

General precautions against scarlet fever.—The body presents a natural resistance to contracting communicable diseases. We do not

catch these diseases unless either the dose of the infecting germ has been sufficient or the natural resistance of the body is deficient.

Attention has already been called to the mouth, nose, and throat as gateways of infection in scarlet fever. Certain diseased conditions of these regions of the body, such as defective teeth, diseased tonsils, and adenoids, probably make them more vulnerable as gateways of infection. Care should be taken, therefore, early to correct such faulty mouth, nose, and throat conditions in children, for by so doing, not only do we strengthen a weak part of the body defenses, but we effect thereby a notable improvement in the general health besides removing conditions known to exert an unfortuanate influence upon the subsequent physical or even the mental development.

While it is realized that it is instinctive for the child habitually to carry all objects to the mouth, it is well worth while, on the part of parents and guardians, to teach children, as early as possible, that the only substances which naturally belong in the mouth are food and drink. The danger of such practices as putting lead pencils, coins, and similar objects in the mouth, the use of the common towel and drinking cup, taking bites of the same apple or stick of candy, the failure to turn the head away when coughing or sneezing, and, in a word, all acts which lead to an exchange of the mouth fluids between human beings should be regarded as one of the earliest and most practical essentials of the education of children.

CURRENT WORLD PREVALENCE OF DISEASE

REVIEW OF THE MONTHLY EPIDEMIOLOGICAL REPORT OF THE HEALTH SECTION OF THE LEAGUE OF NATION'S SECRETARIAT, NOVEMBER 15, 1927 [1]

Plague.--There were few plague cases in the Mediterranean area in September and October. In Egypt no cases were reported from September 4 to October 14. In Greece 6 cases were reported in September and 3 in October, all at Plomarion on the island of Mytilene. In Tunis no plague case had been notified in the 10 weeks ended October 23. In Algeria there was 1 case at Oran and 1 at Philippeville in September and 2 cases at Algiers between October 11 and 15.

At Las Palmas, in the Canary Islands, 4 plague cases were reported on October 10.

Plague incidence in Senegal in September (708 cases) was higher than in any month of the preceding two years. The epidemic seemed to have abated in October. In Nigeria, on the other hand, only 8 cases were reported in August, as compared with 187 cases in the corresponding month of the preceding year. The Report states:

> No plague case has been reported in Angola since March and none in the Union of South Africa since the first week of August. Reunion has been free from plague

[1] From the Office of Statistical Investigations.

since January. Plague has again spread in Madagascar since the beginning of August; 170 cases were reported in September, which is about the same as during the corresponding month of 1926. The season of low plague incidence has come in Kenya and Uganda; the number of cases reported is about the same as last year.

In northern India, during the 13 weeks ended September 24, only 119 cases of plague were reported in the area reaching from Assam in the east to the Northwest Frontier Province in the west. In 1926, 424 cases were reported in this area during the corresponding weeks, and in 1925, 1,298 cases. The incidence in Bombay Presidency, in Madras Presidency, in Mysore, in Hyderabad, and in the central Provinces was somewhat lower than in 1926, but the disease was fairly prevalent; 1,220 cases were reported in all of India in the two weeks ended September 24, nearly all of which were in the aforementioned Provinces.

Information was received from the North Manchuria Plague Prevention Service and from the government of the Kwantung Territory concerning a plague outbreak in September near Payintala (also called Tungliao) in the eastern part of Inner Mongolia. The Report gives the following details:

Payintala is a town of about 20,000 inhabitants and the terminus of a branch railway which joins the South Manchuria Railway system at Chien-Chia-Tun, from which there is a railway to Szepingkai on the Mukden-Harbin line. It is believed that lamas coming from the interior of Mongolia at the end of August brought the infection to the villages situated about 17 miles north of Payintala. Several inhabitants in three small villages in this area were infected and died. Two families lost 14 and 13 members, respectively. Altogether there were 50 or 60 deaths. The symptoms were those of pneumonic and bubonic plague, but cultures were not obtained. The last case occurred on October 3, according to information from Harbin dated October 21. Chinese and Japanese plague prevention services are on the spot and all precautions have been taken on the railway lines.

Cholera.—Cholera was unusually prevalent in Asiatic ports during the past summer and autumn. Twenty-six of the ports reporting to the Singapore bureau were infected at one time or another from July 31 to October 29; and the cases reported numbered 1,657. Many more cases than in the preceding year occurred in ports from Madras westward, but there was less cholera in Bangkok and several other ports in eastern Asia. The situation had improved in October, especially in the ports west of Calcutta. During the four weeks ended November 5, cholera cases were reported, mostly sporadically, in 10 ports—Basrah, Tuticorn, Madras, Calcutta, Rangoon, Singapore, Bangkok, Canton, Amoy, and Shanghai. In the first week of October, an outbreak of cholera was reported at Lingah, a Persian port on the Strait of Ormuz.

In October the cholera epidemic in Iraq was under control in the centers first affected. Abadan and Mohammerah have been free

from cholera since the beginning of September and Basrah had only 3 cases in October. The infection spread, however, farther west and north along the Euphrates.

The incidence of cholera in India, which had remained at a high level ever since the end of March, began to decrease after the middle of September. The deaths in the various provinces are shown by fortnightly periods in Table 1.

TABLE 1.—*Deaths from cholera in the Provinces of India, by fortnightly periods, from June 5 to September 24, 1927*

Province	June 5 to June 18	June 19 to July 2	July 3 to July 16	July 17 to July 30	July 31 to Aug. 13	Aug. 14 to Aug. 27	Aug. 28 to Sept. 10	Sept 11 to Sept. 24
Punjab and Delhi	193	934	1,312	986	275	351	200	158
Punjab States	71	215	269	205	13	37	9	129

	13,151	12,219	11,969	12,233	11,109	11,590	9,885	6,069

* One week only.

A small outbreak of cholera in the Federated Malay States began in June and had terminated early in September; 108 cases and 73 deaths were reported.

Cholera was less prevalent in China during the past summer and autumn than a year ago. The Report states:

In the course of August and September outbreaks occurred at Swatow, Macao, Canton, Hong Kong, Amoy, and Shanghai; but the number of cases was much smaller than in 1926. The infection spread as far north as Tien-Tsin, Chingwang-Tao, Newchwang, and Dairen, but there were only a few cases in each locality.

There has been no cholera this year in Chosen.

Yellow fever.—The Report says:

Twenty cases of yellow fever were reported in September among the European population of Senegal, of which 17 were at Dakar and Goree and 2 at Thies. In October, cases continued to occur at Dakar and Thies and appeared also in various inland localities, especially on the railway line from Dakar through Thies to St. Louis. Twenty cases were reported during the first 18 days of October, of which 5 were at Dakar, 9 at Thies, and 1 at Rufisque, the remainder in small inland villages or smaller towns. Between October 19 and November 2 inclusive, 20 cases were reported, of which 8 were at Dakar and 2 at Thies, the remainder being scattered in six villages. Twelve of these cases were among Europeans, 6 among Syrians and 2 among half-breeds. Preventive measures and search for suspected cases are being actively pursued.

Six cases were reported in September in the Gold Coast Colony, mostly in the Volta River district. According to information up to the end of October, the last case occurred at Accra on September 23 and at Cape Coast on August 10. Two yellow fever cases were reported in Nigeria in September.

Smallpox.—The incidence of smallpox in England and Wales showed a seasonal increase in October, but was not higher than at the corresponding date of 1926.

Smallpox continued very prevalent in Algeria, especially in the Department of Oran. It is less prevalent than in previous years in Tunis and in Egypt.

Smallpox has been more prevalent in 1927 in Nigeria than for several years. According to the report, "3,567 cases and 814 deaths, which mostly occurred in the northern Province, were reported during the first nine months of the current year. The case mortality rate was 22.8 per cent; last year it was 20.6 per cent among hospitalized cases. The number of cases increased from 91 in August to 237 in September."

In India, the smallpox incidence has returned to a more normal level, after severe outbreaks in the first half of the year in Bengal, Bihar and Orissa. In the four weeks ended September 24, 4,440 cases were reported, as compared with 6,738 during the corresponding period of 1926.

The incidence of "alastrim" has declined in Jamaica, "202 cases having been reported during the first nine months of the current year as compared with 961 cases during the corresponding period last year. The number of cases has usually been between 1,000 and 2,000 in previous years."

Enteric fever.—"Enteric fever is less prevalent in Germany, the Netherlands, and Sweden than in any previous year," states the Report. "In other European countries, there was no marked improvement in comparison with last year; in some countries the incidence was considerably higher than usual. More cases than last year were, for instance, reported in all the countries southeast of a line drawn from Poland to Italy. In Italy, there were 6,268 cases during the four weeks ended September 4, as compared with 4,415 during the corresponding period of the preceding year. In Greece, 2,012 cases were reported during the first nine months of the year, as against 523 cases during the corresponding period of 1926. The incidence was higher than usual in Egypt."

Dysentery.—In Germany the incidence of dysentery was lower in recent months than in previous years; only half as many cases were reported in October as during the corresponding month of 1926. On the other hand, there were more cases than last year in Poland, where 1,102 cases were reported during the four weeks ended October

15, as compared with 719 cases during the corresponding period of the preceding year. There was a marked increase over last year also in Rumania. The fluctuations in dysentery from year to year in these countries seem to correspond with those for enteric fever, but the former are greater than those of enteric fever, according to the Report.

Acute poliomyelitis.—There was a general decline in the incidence of poliomyelitis in October. Among countries for which reliable statistics are available, the incidence was markedly higher than in the preceding year only in the United States, Germany, Austria, and Sweden.

The outbreaks in Germany reached their maximum during the last week of September, when 240 cases were reported. The area principally affected comprises the districts of Leipsig and Merseburg, in which the epidemic was particularly severe, Dresden, Chemnitz, Magdeburg, Potsdam, Arnsberg, Cassel, and Thuringia.

The incidence of poliomyelitis in 1927 and in previous years in various European countries is shown in Table 2.

TABLE 2.—*Poliomyelitis cases reported in various European countries during the first nine or ten months of the years 1923–1927*

Country	Jan. 1 to—	1923	1924	1925	1926	1927
England and Wales	Nov. 5	521	744	361	994	788
Sweden	Oct. 31	215	555	438	286	293
Finland	Oct. 15	36	39	23	11	45
Denmark	Sept. 30	42	91	86	41	21
Germany	Oct. 22	-----	393	312	1,329	2,088
The Netherlands	Nov. 5	-----	34	31	44	26
Switzerland	do	193	93	81	82	91
Austria	Oct. 15	-----	-----	8	23	115
France	Sept. 30	132	168	153	148	113
Italy	Sept. 4	-----	-----	411	217	164

Diphtheria.—In recent months, according to the Report, there has been an increase in diphtheria over the 1926 incidence in nearly all European countries, although the 1926 incidence was higher than that for preceding years in most countries. Comparison of recent statistics for 1927 with corresponding figures for 1926 is given in Table 3.

TABLE 3.—*Comparison of diphtheria prevalence, 1926 and 1927*

Country	Period	Number of cases	
		1926	1927
England and Wales	Oct. 9–Nov. 5	4,562	5,608
Sweden	October	349	471
Germany	Sept. 25–Oct. 22	2,331	2,760
Poland	do	708	957
Czechoslovakia	Sept. 16–Oct. 15	492	774
Italy	Aug. 8–Sept. 4	736	957

Similarly in the United States, where the incidence of diphtheria had decreased steadily since 1921, the October incidence exceeded that for October, 1926.

Scarlet fever.—Most European countries showed a lower incidence for scarlet fever in September and October than at the corresponding season of 1926. In Sweden, Poland, and the Baltic Republics teh decrease was very marked. There was an increase, on the other hand, in England and Wales, Germany, Austria, Czechoslovakia, the Kingdom of the Serbs, Croats and Slovenes, and Bulgaria.

The mortality from scarlet fever in 1926 in the principal towns of Europe indicates that the disease causes a much heavier mortality in Russia and Poland than in central, northern, and western Europe.

DEATH RATES IN A GROUP OF INSURED PERSONS

Rates for Principal Causes of Death for September and October, 1927

The accompanying tables are taken from the Statistical Bulletin for October and November, respectively, published by the Metropolitan Life Insurance Co., and present the mortality experience of the industrial department of the company for September and October, 1927, as compared with the preceding months and with the corresponding months of 1926. The rates are based on a strength of approximately 18,000,000 insured persons in the United States and Canada.

SEPTEMBER, 1927

The death rate for September was 8.0 per 1,000, as compared with 8.1 for August and with 8.3 for September a year ago. The rate this year is the lowest recorded for the month of September since 1923, when it was 7.9 per 1,000. The rate also shows a slight improvement over that for the preceding month.

The typhoid fever death rate, for the first time since the beginning of the Montreal outbreak last spring, recorded a lower figure than for the corresponding month last year; and for the first month in 1927 the diphtheria death rate was not higher than for the corresponding month a year ago.

Favorable conditions for September were also shown for tuberculosis and diarrheal complaints.

Death rates (annual basis) for principal causes per 100,000 lives exposed, September, 1927, as compared with August, 1927, and with September, 1926

Cause of death	Rate per 100,000 lives exposed[1]			
	September, 1927	August, 1927	September, 1926	Year 1926
Total, all causes	801.4	806.8	826.5	945.6
Typhoid fever	5.2	5.6	8.5	4.2
Measles	.5	1.7	1.9	10.2
Scarlet fever	1.6	1.8	1.1	3.4
Whooping cough	6.4	7.0	9.1	9.6
Diphtheria	6.6	7.5	6.6	9.7
Influenza	5.2	4.5	4.7	31.1
Tuberculosis (all forms)	80.7	90.6	90.9	99.0
Tuberculosis of respiratory system	70.3	79.3	80.2	86.7
Cancer	72.7	74.3	73.9	73.7
Diabetes mellitus	14.3	15.4	15.3	16.7
Cerebral hemorrhage	49.9	44.6	46.8	55.6
Organic diseases of heart	114.8	114.6	106.7	134.3
Pneumonia (all forms)	37.3	38.2	36.8	98.2
Other respiratory diseases	12.8	11.2	9.1	13.0
Diarrhea and enteritis	47.0	35.9	64.5	29.8
Bright's disease (chronic nephritis)	62.8	61.0	61.3	73.5
Puerperal state	12.5	14.6	11.7	15.3
Suicides	8.0	8.7	9.1	7.7
Homicides	5.3	6.9	6.6	7.0
Other external causes (excluding suicides and homicides)	68.2	73.1	69.6	62.3
Traumatism by automobiles	22.2	19.7	20.9	16.8
All other causes	189.7	189.6	192.0	191.0

[1] All figures include infants insured under 1 year of age.

OCTOBER, 1927

The death rate for this group of persons for October, 7.7 per 1,000, was not only the lowest rate reported for any month during the current year, but the lowest recorded for this month in the records of the company.

The typhoid fever death rate continued to decline and was 3.7 per 100,000 as compared with 5.2 for September and with 6.3 for October a year ago.

The diphtheria situation also showed improvement over last year, the death rate for October being 9.6 as compared with 10.6 in 1926. The other three principal diseases of childhood registered lower mortality than in October last year.

The tuberculosis death rate shows a decline from the rate for 1926; in fact, with a single exception, every month of 1927 has shown improvement over 1926 in tuberculosis mortality, and a new low figure for this disease seems assured for 1927.

Influenza, pneumonia, diarrheal complaints, and Bright's disease are other important causes of death to show lower rates in October than were recorded a year ago, while the number of deaths from cancer, diabetes, cerebral hemorrhage, and heart disease increased—slightly in each instance.

Death rates (annual basis) for principal causes per 100,000 lives exposed, October, 1927, as compared with September, 1927, and with October, 1926

Cause of death	Rate per 100,000 lives exposed [1]			
	October, 1927	September, 1927	October, 1926	Year 1926
Total, all causes	769.7	801.1	797.7	945.6
Typhoid fever	3.7	5.2	6.3	4.2
Measles	.4	.5	1.3	10.2
Scarlet fever	1.5	1.6	2.1	3.4
Whooping cough	4.1	6.4	6.1	9.6
Diphtheria	9.6	6.6	10.6	9.7
Influenza	6.5	5.2	7.0	31.1
Tuberculosis (all forms)	74.7	80.7	79.3	99.0
Tuberculosis of respiratory system	66.5	70.3	69.9	86.7
Cancer	71.6	72.7	70.7	73.7
Diabetes mellitus	15.0	14.3	11.1	16.7
Cerebral hemorrhage	49.0	49.9	47.1	55.6
Organic diseases of heart	112.0	111.8	108.3	131.3
Pneumonia (all forms)	46.3	37.3	49.4	98.2
Other respiratory diseases	12.6	12.8	11.2	13.0
Diarrhea and enteritis	36.6	47.0	50.0	29.8
Bright's disease (chronic nephritis)	60.5	62.8	63.0	73.5
Puerperal state	12.6	12.5	12.0	15.3
Suicides	7.4	8.0	8.0	7.7
Homicides	6.8	5.3	6.4	7.0
Other external causes (excluding suicides and homicides)	62.1	68.2	58.9	62.3
Traumatism by automobiles	20.3	22.2	19.8	16.8
All other causes	176.4	189.7	185.8	191.0

PUBLIC HEALTH ENGINEERING ABSTRACTS

Feeding Garbage to Hogs. F. G. Ashbrook and A. Wilson, U. S. Dept. of Agriculture Farmers' Bulletin No. 1133. 24 pages. (Abstract by Arthur P. Miller.)

This bulletin is prepared from the viewpoint of hog feeding and not of garbage disposal.

Some observations made are of interest, however. (1) Waste food products of more than 8,000,000 people are fed to hogs and fully 40,000,000 pounds of pork are thus produced and sold annually; (2) a ton of municipal garbage may be expected to produce 40 pounds of live weight of hog; (3) garbage used must be reasonably fresh and free from injurious foreign articles; (4) it is better for the city to handle garbage collection and then dispose of garbage to the hog feeder. Long-time contracts with the feeder tend to produce best results.

Street Cleaning and Refuse Disposal in Columbus, Ohio. H. L. Killiam. *Public Works*, vol. 58, No. 9, September, 1927, pp 330-331. (Abstract by E. L. Filby.)

Statistical data as to costs of operation and methods of arriving thereat are given. Flushing thrice weekly gave as good results as daily hand patrol and at reduced cost.

Refuse collection includes garbage and dead animals. Garbage amounted to 20.68 pounds per capita per year. Cost was 10 per cent greater than in 1925. Manure is sold by car and wagon loads.

Garbage disposal by digestion with grease and tankage recovery. From 30,614 tons of garbage, 729 tons of grease, 2,383 tons of tankage, and 8 hides were recovered. Sales averaged $3.596 per ton of green garbage, and operation maintenance charges were $3.155, or gross operating profit $0.441 per ton.

Garbage Collection at Victoria, B. C. F. M. Preston. *Canadian Engineer*, vol. 53, No. 3, July 19, 1927, pp. 141-142. (Abstract by R. E. Thompson.)

All waste material is trucked to a central wharf, where it is dumped into scows and finally disposed of at sea. No charge is made for collection from residences, but all types of business establishments are charged 15 cents per can collected. A standard size can is insisted upon and anything but garden refuse may be placed in it. These cans, having a capacity of 3½ cubic feet, are made at the city's shops and are rented out for the lifetime of the can at $4.20 each. When a can has reached the end of its useful life a printed notice of the fact that it must be renewed is left at the particular house, and when next collection becomes due the old can is removed. During the year 1926 the amount of refuse collected from residential districts was 21,701 cubic yards, and from commercial districts 3,280 cubic yards. The total sum expended during the year was $29,000, of which $5,507 was expended on the contract for towing to sea and dumping.

Paranasal Sinus Infection and Swimming. Frederick E. Hasty, *Journal American Medical Association*, vol. 89, No. 7, August 13, 1927, pp. 507–509. (Abstract by C. H. Kibbey.)

The types of bacteria found in diseases of the paranasal sinuses, middle ear, and upper respiratory tract have received little consideration. These infections have become so frequent that almost every family has suffered as a result of swimming. The author has made a number of interesting tests in the hope of determining some of the important factors entering into the problem.

Attention is called to the fact that most bacteriological examinations of water are made from the standpoint of gastro-enteric infections, and while this is sufficient for drinking water, where water for swimming is being considered the type of bacteria present may be even more important than is the relative number of bacteria it contains.

It is not considered possible completely to sterilize swimming pools. Filtration and the ultra-violet ray are comparatively satisfactory, but chlorine, in one form or another, has proved one of the most satisfactory chemicals. The water used in the author's studies was taken from pools where one of the above methods was employed and he is unable to determine any difference in the results of either method.

The water in a pool during the time of swimming represents the combined washings of the nasal and oral mucous membranes of every swimmer. This fact the author demonstrated in a novel and interesting manner which is conclusive, establishing the fact that water gets well into the nasal chambers of the majority of swimmers, carrying with it contamination from the pool and adding to the pool any organisms washed from the swimmer's nose.

A number of observations were made regarding the effect of water on the mucous membrane adjacent to the ostia of the anterior group of paranasal sinuses, and logical deductions are made regarding the introduction of harmful organisms, together with the possible creation of a favorable environment for their reproduction.

A number of experiments were made with laboratory animals in an effort to produce paranasal sinus infections. A serious obstacle to the use of pigs for this purpose was encountered in the marked dissimilar anatomic structure of these animals as compared to man. An effort was made to overcome structural differences, however, by fixing the animals in such a position that water, once introduced into the antrums, did not readily drain out.

It is of interest that two of the pigs which died, one on the fourth and one on the fifth day, showed *Bacillus coli* and streptococci present in the heart blood on post mortem examination. The control pig continued to thrive.

The author's clinical observations are as follows: (1) The sinus infections resulting from swimming are often severe; (2) children are especially liable to infections; (3) persons who have previously suffered from paranasal infections

or nasal obstructions are liable to acute attacks following swimming; (4) the high percentage of infections is due to virulent organisms reaching vulnerable parts of the nose, etc.

Attention is called to the fact that man is not an aquatic animal and has a lack of adaptability to aquatic life.

Presedimentation of Turbid Water Supplies. A. W. Bull and G. M. Darby. (Trans. Am. Inst. Chem. Eng. 18,365–78 (1927).) From *Chemical Abstracts*, vol. 21, No. 21, Part I, November 10, 1927, p. 3694. (Abstract by Foster D. Snell.)

"Presettling reduced the suspended solids by 85–95 per cent. A three-hour presedimentation reduced the coagulants required to approximately half the amounts for direct treatment. Presedimentation reduces the accumulation of solids in the coagulation basin, reduces the cost of cleaning, and saves the cost of chemical treatment of the water discharged with the sludge from presettling. When water is to be softened there is also a saving in lime. The Dorr clarifier reduces the sludge volume approximately 30 per cent below that obtained by direct sedimentation. Results at seven points on the Mississippi, Missouri, and Arkansas Rivers were about the same. Clarifier and laboratory results at Jefferson City were closely parallel."

San Fernando Chlorination Plant, Los Angeles. Carl Wilson. *Western Construction News*, vol. 2, No. 19, October 10, 1927, pp. 73–75. (Abstract by E. A. Reinke.)

The Los Angeles water department has recently completed an automatic chlorination plant treating a maximum flow of 175,000,000 gallons daily. Wallace and Tiernan vacuum automatic machines, using Pitot tubes instead of Venturi tubes, are employed. Six machines, each of 150-pound daily capacity, are used, four feeding a 72-inch and two feeding a 54-inch trunk. Three electrically-driven Quimby screw pumps are used to supply water to injectors, any one of which will handle normal operation. The pumps come into service automatically as the pressure drops below 125 pounds, and in the event of power interruption an automatically starting Novo 4-cylinder, 25-horsepower gasoline engine operates a Worthington triplex pump of sufficient capacity to supply injector water. Chlorine is purchased in 1-ton drums, handled by overhead cranes, and weighed on 5-ton platform scales which are sensitive to one-half pound. The cost of Mission type, tile-roofed building was $7,500, and of the equipment, $22,000. Thirty samples, representing each subdivision of the Los Angeles water supply, are collected daily, including Sundays and holidays. All samples from San Fernando after chlorination show absence of *B. coli* in 50 cubic centimeters.

How to Increase Ground Water Supplies. W. G. Kirchoffer. *Water Works Engineering*, vol. 80, No. 15, July 20, 1927, pp. 1075 1076. (Abstract by M F. Trice.)

The subject is divided into eight different divisions, in each one of which the method of forming the well and the ground conditions determining its classification are discussed briefly. The flow of water may be increased by a variety of methods, depending on the type of well. Some of the practices mentioned are reaming out with or without recasing; shooting with explosive, increasing the depth; back blowing with air; brushing out; cleaning screens; increasing cavity in loose sand; sinking new cylinder; sinking porous concrete wall. Subsurface dams across valleys are mentioned. Procedure a town should follow in securing new supply is briefly discussed and the increased cost of having inexperienced men do the prospecting is pointed out.

A Study of the Sanitary Significance of Air in Relation to Ice Cream. F. W. Fabian. (Michigan Sta. Tech. Bul. 83 (1927), pp. 30). From Experiment

Station Record, U. S. Dept. of Agriculture, vol. 57, No. 7, November, 1927, pp. 668–69.

"The work reported is divided into two parts:

"I. A study of the bacteria in the air of an ice cream plant, pp. 3–19. Tests were made during each month of the year to determine the number of bacteria in the air in the room where the ice cream was mixed, Pasteurized, homogenized, cooled, and frozen. The fewest bacteria were found during January and the most in April. Weather was the most important factor in determining the number of bacteria present. Other factors were doors and windows, floor, and machinery. Samples indicated that there were more bacteria in the air near the outside walls than near the inside walls, and in the same manner more near the inside walls than in the center of the room.

"The author concludes that bacterial contamination from the air was insignificant. The majority of the bacteria found were peptonizers and alkali—producing the inert bacteria. A few weak acid-forming bacteria were found, but practically no strong acid-forming. Fewer molds than bacteria were present.

"II. A study of the amount of air taken into a freezer during the freezing of ice cream mix, pp. 20–29. In this work the freezer was made air-tight and an apparatus devised whereby the air entering the chamber could be measured. It was found that the amount of air that normally enters a freezer during operation is very small. It was found possible to make ice cream of normal overrun when all openings were made air-tight, and in a few cases where a partial vacuum was established in the freezer a normal overrun was obtained by lengthening the time of whipping somewhat. The author recommends that all openings of the freezer be kept closed during the freezing process, for sanitary reasons."

When is a Milk Bottle Clean? Milton E. Parker. *The Nation's Health*, vol. 9, No. 10, October, 1927, pp. 31–33 and 66. (Abstract by J. H. O'Neill.)

A clean bottle must not only be practically free from bacterial contamination, and especially from harmful types, but should also be equally as free from any physical contamination. Investigations have established a count of 100 bacteria per quart bottle as a reasonable bacterial standard for testing efficiency of milk-bottle sterilization. Units to measure physical cleanliness are not available. Perhaps the best method available at the present time is to wet the surface with distilled water and watch for a break in the film. Freedom from oily or dirty films upon the application of distilled water serves as a reasonable standard of physical cleanliness.

Investigations have shown that colloidal alkalies contribute a combined detergency and antisepsis under practical working conditions superior to that afforded by the usual cleaning methods. The germicidal action of most detergents is due mainly to their degree of hydroxyl iron concentration.

The Disposal of the Sewage of the Sanitary District of Chicago. Division of State Water Survey, Urbana, Ill., Bulletin No. 23, February, 1927. 195 pages. (Abstract by I. W. Mendelsohn.)

This report treats fully of the disposal of the sewage of the Sanitary District of Chicago. There are many tables, charts, and maps which contain data combed from the whole field of sewage disposal. The subject is considered in the following sections: Present disposal of sewage and deficiencies, population and growth, amount and quality of sewage, standard of maximum pollution, required degree of purification with various dilutions, protection of the water supply, savings affected by metering, volume of sewage, future intercepting sewer construction, methods of sewage disposal and practicable efficiencies, sewage disposal costs in other cities, and required works for various diversion flows.

Conclusions: The summarized conclusions include the following: (1) The diversion of the Chicago sewage from Lake Michigan, resulting from the drainage canal

and other causes, has effected a remarkable improvement in the death rate from water-borne diseases. (2) The present discharge of the sewers within the sanitary district is about 800,000,000 gallons per day. This sewage carries an organic load per capita greater than that of any other large city for which accurate figures have been available. (3) In the consideration of sewage-treatment works that will be required under various drafts of dilution water from Lake Michigan, it has been necessary to fix a standard of maximum pollution for the Chicago Drainage Canal in order that reasonable sanitary conditions may be maintained in the Des Plaines and Illinois Rivers. The following is suggested as a reasonable standard: The liquid discharged by the drainage canal, as evidenced by the average of representative samples taken for any 30 consecutive days shall—(*a*) be practically free from settleable solids deposited in two hours; (*b*) contain dissolved oxygen equal to or exceeding the biochemical oxygen demand of said liquid for five days when incubated at 20° C., (*c*) contain not less than three parts per million of dissolved oxygen. (4) Even under the heavy diversions from Lake Michigan in recent years and the generally favorable typhoid death rate, the quality of the water supply for Chicago has been far from satisfactory. Chicago can secure pure clean water at all times by the filtration of its present supply. Filtration is considered as a prerequisite to the adequate disposal of sewage. (5) At the present time 90 per cent of all water services in Chicago are served through so-called "flat rates." Universal metering of the water services is urgent. Metering alone will (*a*) double the average pressure within the city; (*b*) furnish *all* adequate water service where but 25 per cent now enjoy it; (*c*) enable the present water works with but minor extensions to serve the city for the next generation; and (*d*) through the immense savings effected in deferred construction costs enable the city to install filtration works.

If universal metering of the Chicago water works is accomplished within the next 10 years, savings of from $200,000,000 to $225,000,000 will be effected prior to 1945. This amount is so great that, in addition to financing the installation of meters and filtration works for the entire city, it would cover the cost of constructing the entire intercepting sewer and sewage disposal works required in the Chicago Sanitary District up to 1945 and leave a large surplus in addition. (6) The installation of meters on all services will cause the sewage flow of 1945 under complete metering to be less than at the present time. (7) The sanitary district has adopted tunnels for its intercepting sewers. It is believed that a 35-year period (i. e., to 1960) is that for which the design of interceptors should be economically and practically made for sewers constructed in tunnel, capable of duplication in the future without excessive costs. (8) Construction and operating costs of sewage pumping stations and treatment works in the Sanitary District of Chicago in comparison with similar costs in other cities are from two to eight times as great.

Studies on Film Accumulation in the Sprinkling Filter Bed. W. Rudolfs and D. Peterson. Report of the Sewage Substation of the New Jersey Agricultural Experiment Station for year ending June 30, 1926, pp. 498–505. (Abstract by W. M. Olson.)

To learn more about the physical nature of the film upon the stones and the cause of its accumulation and sloughing, this study was made. Conclusions are from weekly determinations of moisture, solid matter, and organic and ash contents of solids. Film one week old was compared with film accumulating from one sloughing period to the next, and with film in the process of sloughing. Data are presented in a table and in four diagrams which would be benefited by more explanation.

Samples of film were scraped from tiles arranged in a cabinet set in the filter bed. Wet film was deposited at an average rate of 3.5 grams per week per tile.

(Tiles 6 by 3 by ⅜ inches—Third Annual Report of the Sewage Substation for the year ending June 30, 1924, p. 50.) The wet weekly film deposit contained 4 per cent solids, of which 18 per cent was ash. A 16 weeks' accumulation of wet film weighed from 15 to 50 grams per tile. The rate of film deposit was not uniform throughout the bed. Opercularia was the dominant protozoan in the film. Nitrification is best shortly after sloughing and decreases with increase in thickness of film. Studies will be made concerning artificial control of film thickness.

Film is built up by organisms utilizing colloidal carbon compounds in the applied liquid, by carbonates and sulphates absorbed from solution, by ash deposited in oxidation, and by excreta of large organisms.

The seasonal slough may be due to the weight of old film, the seasonal succession of fungi and the favorable habitat for large metazoan animals in the old film.

"The design of a filter bed should depend on the amounts of solids to be handled." At Plainfield, with 75 p. p. m. suspended solids, the beds must be at least 6 feet deep.

The Treatment of Beet Flume and Washer Waters. Paul Hirshfelder. *Centr. Zuckerind.* 35, 273–4 (1927). From *Chemical Abstracts*, vol. 21, No. 22, Part I, November 20, 1927, p. 3997. (Abstract by W. L. Badger.)

"Such waters may be treated by (*A*) simple settling basins. The first cost is small, but the cost of sludge disposal is heavy, and trouble is experienced because of putrefaction in the sludge. (*B*) The waste water may be pumped into fields, which are used for cultivation after a layer of sludge has built up. This involves heavy charges for land, and the results are not satisfactory, because of the settling of sand in the nearer areas. (*C*) Small settling basins with continuous sludge removal may be used, and the heavy sludge formed pumped to waste land. This is often satisfactory, especially where the sludge need not be pumped far. (*D*) Where sludge must be transported over 2 kilometers, a settling basin with a slow-moving rake should be used to produce a sludge of not over 10–15 per cent solids. This may be pumped without undue expense and without danger of sand settling out."

South Australian Waterworks and Sewerage Systems. Herbert E. Bellamy. *Journal Royal Sanitary Institute*, vol. 57, No. 9, March, 1927, pp. 583–587. (Abstract by A. H. Fletcher.)

The author describes the waterworks for the city of Adelaide, the capital of South Australia, which consists of four reservoirs of a combined capacity of 7,748 million gallons. The rainfall on 305 square miles of catchment area is utilized and supplies a population of 230,000. The Metropolitan District covers an area of 175 square miles. The length of mains is 1,108½ miles.

Country water districts have been formed. The principal country districts are the Beetaloo, Barossa, Warren, Bundaleer, and Tod River, in which 82 towns, as well as country lands, are supplied. There are 2,740½ miles of cast-iron mains supplying these districts.

In the year 1878 an act of Parliament was passed making provision for the necessary expenditure to construct a complete sewerage system for Adelaide. This was the first city in Australia for which a complete sewerage system combined with a sewage farm for the disposal of the sewage was adopted. It is now proposed to abandon the farm and to construct treatment works of the activated sludge system.

Relation of Regional Plan Work to Public Health Engineering. Howard E. Long. *American Journal of Public Health*, vol. 17, No. 10, October, 1927, pp. 1014–1017. (Abstract by H. N. Old.)

Attention is directed in this article to the cooperation which should exist between sanitary engineers and those engaged in regional planning, the goal of

both groups being that of providing adequate and unadulterated air, light, food and water with proper disposal and elimination of waste products on a community basis with due consideration of the economics of the problem.

The regional planner is concerned more particularly in planning and developing adequate present and future means of accomplishing facility of supply, as well as purity of supply, while the public-health engineer is responsible for the operation and maintenance of the facilities afforded.

While it is stated that some interests of the public-health worker are beyond the scope of the planner, the "health engineer and the planning engineer meet on common ground and should cooperate to the fullest possible extent in subjects wherein community of interest and regional attention to futures are indicated. For example, in the field of sewage disposal, food and water supply, air and light, housing and zoning, recreation, hospital and convalescent facilities, and education, the work of the planner augments that of the sanitarian, and vice versa."

Under the subtitles sewerage, water supply, food supply, hazards to health, modern era one of tremendous nervous strain, recreation and quiet, schools, and burial places, the author elaborates somewhat on specific conditions upon which these two groups of public-service engineers should more or less dovetail their efforts.

Particular stress is placed by the author upon the advantages of central heating systems in communities where this plan is feasible, a project which has received too little attention up to this time on the part of sanitarians and regional planners.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 98 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 30,390,000. The estimated population of the 92 cities reporting deaths is more than 29,720,000. The estimated expect-

ancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended December 24, 1927, and December 25, 1926

	1927	1926	Estimated expectancy

City reports for week ended December 24, 1927

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1918 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended December 24, 1927, compared with those for a like period ended December 25, 1926. The population figures used in computing the rates are approximate estimates as of July 1, 1926 and 1927, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 30,445,000 in 1926 and 30,966,000 in 1927. The 95 cities reporting deaths had nearly 29,785,000 estimated population in 1926 and nearly 30,296,000 in 1927. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, November 20 to December 24, 1927—Annual rates per 100,000 population, compared with rates for the corresponding period of 1926 [1]

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended December 17, 1927.—The following report for the week ended December 17, 1927, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

Egypt.—Alexandria.
India.—Bassein, Rangoon.

CHOLERA

India.—Tuticorin, Calcutta, Rangoon.
French India.—Pondicherry.
Straits Settlements.—Singapore.
Siam.—Bangkok.

SMALLPOX

Aden Protectorate.—Aden.
India.—Bombay, Calcutta, Madras, Rangoon.
Dutch East Indies.—Belawan-Deli.
Sarawak.—Kuching.
French Indo-China.—Saigon.
Manchuria.—Mukden.

Returns for the week ended December 17 were not received from Basra, Iraq; Bandjermasin, Dutch East Indies; Canton, China; or Vladivostok, Union of Socialist Soviet Republics.

ANGOLA

Communicable diseases—September, 1927.—During the month of September, 1927, communicable diseases were reported in Angola as follows:

Disease	Coast districts	Interior	Land frontier	Total
Ancylostomiasis	4	3		7
Beriberi	1			1
Bilharzia	2	3		5
Cerebrospinal meningitis	2			2
Chicken pox	12	1		13
Dysentery	27	28	5	60

Tetanus	1	1	1	3
Trypanosomiasis [2]	94	25	23	142
Tuberculosis	19	5	2	26
Typhoid fever	4		1	5
Venereal diseases	106	38	42	186
Whooping cough	5			5
Yaws	70	88	21	179

[1] 2,708 vaccinations performed.
[2] Of unknown nature; 6,260 atoxylizations made.

Yellow fever—Kongo River ports—January 3, 1928.—Information dated January 3, 1928, shows seven cases of yellow fever reported at the ports of Boma and Matadi, Kongo River.

CANADA

Communicable diseases—Week ended December 17, 1927.—The Canadian Ministry of Health reports cases of certain communicable diseases from six Provinces of Canada for the week ended December 17, 1927, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever	1				1		2
Influenza	3			1			4
Smallpox				2	15	6	23
Typhoid fever		4	18		1	2	25

Vital statistics—Quebec—October, 1927.—Births and deaths in the Province of Quebec for the month of October, 1927, were reported as follows:

Estimated population	2,604,000	Deaths from—Continued.	
Births	6,061	Diphtheria	44
Birth rate per 1,000 population	27.93	Heart disease	276
Deaths	2,709	Influenza	30
Death rate per 1,000 population	12.48	Measles	11
Deaths under 1 year	862	Pneumonia	148
Infant mortality rate	142.22	Poliomyelitis	2
Deaths from—		Scarlet fever	14
Accidents (all)	85	Syphilis	2
Cancer	155	Tuberculosis (pulmonary)	144
Cerebrospinal meningitis	7	Tuberculosis (other forms)	39
Diabetes	21	Typhoid fever	21
Diarrhea	234	Whooping cough	30

CANARY ISLANDS

Plague—Las Palmas—November 23, 1927.—Under date of November 23, 1927, the occurrence of a new case of plague was reported at Las Palmas, Canary Islands.

DAHOMEY

Yellow fever—Grand Popo—November 21, 1927.—One fatal case of yellow fever (European) was reported as having occurred on November 21, 1927, at Grand Popo, Dahomey.

IRAQ

Cholera—November 6–19, 1927—Summary to November 19, 1927.—During the two weeks ended November 19, 1927, cholera was reported in Iraq as follows:

Place	Week ended—				Summary to Nov. 19, 1927	
	Nov. 12, 1927		Nov. 19, 1927			
	Cases	Deaths	Cases	Deaths	Cases	Deaths
Amarah	3	3	2	2	183	145

Hillah	5	1	53	29	87	50
Kerbala	2	2	2	2	43	31
Kut	5	3			34	22
Muntafiq	4	2	14	10	207	131
Ramadi	27	14	21	16	85	63
Total	60	27	102	62	1,179	839

SALVADOR

Mortality, general—Mortality from communicable diseases—July–September, 1927.—During the three months ended September 30, 1927, 7,604 deaths from all causes were reported in the Republic of Salvador. Population as of June 30, 1927, 1,600,000. Deaths from certain communicable diseases were reported as follows: Diphtheria, 4; gastroenteritis, 210; measles, 54; tuberculosis, 174; typhoid fever, 11. The general mortality for the three months separately, was, July, 2,737 deaths; August, 2,533; September, 2,334.

SENEGAL

Plague—Two weeks ended December 11, 1927.—A few isolated cases of plague were reported for the week ended December 11, 1927, in the Baol region.

Yellow fever.—There were 5 fatal cases of yellow fever reported at Dakar, Senegal, during the two weeks ended December 11, 1927.

VIRGIN ISLANDS

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported in the Virgin Islands of the United States as follows:

Island and disease	Cases	Remarks
St. Thomas and St. John:		
Dengue	7	
Gonorrhea	4	
Pellagra	2	
St. Croix:		
Gonorrhea	1	
Syphilis	14	Secondary.
Uncinariasis	5	Necator americanus.

YUGOSLAVIA

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported in Yugoslavia as follows:

Disease	Cases	Deaths	Disease	Cases	Deaths
Anthrax	51	7	Measles	2,728	18
Cerebrospinal meningitis	3	1	Poliomyelitis	2	
Diptheria	331	60	Scarlet fever	1,834	238
Dysentery	104	7	Tetanus	20	1
Leprosy	1		Typhoid fever	647	79
Lethargic encephalitis	3		Typhus fever	1	

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

ADDITIONAL COPIES
OF THIS PUBLICATION MAY BE PROCURED FROM
THE SUPERINTENDENT OF DOCUMENTS
U.S. GOVERNMENT PRINTING OFFICE
WASHINGTON, D. C.
AT
5 CENTS PER COPY
SUBSCRIPTION PRICE, $1.50 PER YEAR

PUBLIC HEALTH REPORTS

VOL. 43 JANUARY 20, 1928 NO. 3

PREVALENCE OF SCARLET FEVER IN THE UNITED STATES

Preliminary reports of cases of scarlet fever from the health officers of 37 States for 52 weeks of the years 1925, 1926, and 1927 show that the disease was more prevalent during 1927 than it was during the two preceding years. The figures are as follows:

	Cases
1925	135, 937
1926	143, 150
1927	158, 978

The estimated population of these States was 86,571,000 in 1925 and 90,482,000 in 1927.

The number of cases of scarlet fever reported by these 37 States for the last eight weeks of the year was less in 1927 than it was in either 1925 or 1926. The following table gives a comparison of the reports by four-week periods for the last 20 weeks of the years 1925 to 1927, inclusive:

Four weeks ended—	Corresponding week		
	1927	1926	1925
Sept. 10, 1927	3, 419	3, 121	2, 812
Oct. 8, 1927	5, 378	5, 624	4, 294
Nov. 5, 1927	8, 586	9, 823	8, 122
Dec. 3, 1927	10, 860	13, 330	11, 617
Dec. 31, 1927	11, 943	13, 876	12, 222
Total	40, 186	45, 774	39, 067

HOW TO GIVE ARTIFICIAL RESPIRATION BY THE PRONE PRESSURE METHOD[1]

1. Lay the patient on his belly, one arm extended directly overhead, the other arm bent at elbow and with the face turned outward and resting on hand or forearm so that the nose and mouth are free for breathing. (See fig. 1.)

2. Kneel straddling the patient's thighs with your knees placed at such a distance from the hip bones as will allow you to assume the position shown in Figure 1.

[1] This method has been approved by the following organizations: American Telephone & Telegraph Co.; American Red Cross; American Gas Association; Bethlehem Steel Co.; National Electric Light Association; National Safety Council; Bureau of Medicine and Surgery, Navy Department; Office of the Surgeon General, War Department; U. S. Bureau of Mines; U. S. Bureau of Standards; and U. S. Public Health Service.

Place the palms of the hands on the small of the back with fingers resting on the ribs, the little finger just touching the lowest rib, with the thumb and fingers in a natural position, and the tips of the fingers just out of sight. (See fig. 1.)

3. With arms held straight, swing forward slowly so that the weight of your body is gradually brought to bear upon the patient. The shoulder should be directly over the heel of the hand at the end of the forward swing. (See fig. 2.) Do not bend your elbows. This operation should take about two seconds.

4. Now immediately swing backward so as to remove the pressure completely. (See fig. 3.)

5. After two seconds, swing forward again. Thus repeat deliberately twelve to fifteen times a minute the double movement of compression and release, a complete respiration in four or five seconds.

6. Continue artificial respiration without interruption until natural breathing is restored, if necessary, four hours or longer, or until a physician declares the patient is dead

7. As soon as this artificial respiration has been started and while it is being continued, an assistant should loosen any tight clothing about the patient's neck, chest, or waist. *Keep the patient warm.* Do not give any liquids whatever by mouth until the patient is fully conscious.

8. To avoid strain on the heart when the patient revives, he should be kept lying down and not allowed to stand or sit up. If the doctor has not arrived by the time the patient has revived, he should be given some stimulant, such as one teaspoonful of aromatic spirits of ammonia in a small glass of water or a hot drink of coffee or tea, etc. The patient should be kept warm.

9. Resuscitation should be carried on at the nearest possible point to where the patient received his injuries. He should not be moved from this point until he is breathing normally of his own volition and then moved only in a lying position. Should it be necessary, due to extreme weather conditions, etc., to move the patient before he is breathing normally, resuscitation should be carried on during the time that he is being moved.

10. A brief return of natural respiration is not a certain indication for stopping the resuscitation. Not infrequently the patient, after a temporary recovery of respiration, stops breathing again. The patient must be watched and if natural breathing stops, artificial respiration should be resumed at once.

11. In carrying out resuscitation it may be necessary to change the operator. This change must be made without losing the rhythm of respiration. By this procedure no confusion results at the time of change of operator and a regular rhythm is kept up.

A RESURVEY OF ENDEMIC THYROID ENLARGEMENT IN CINCINNATI

By Robert Olesen, *Surgeon United States Public Health Service*

The incidence of endemic thyroid enlargement among the school children of Cincinnati was less in 1927 than it was in 1924. Moreover, there was a notable decrease in the number of enlargements of considerable size during the three-year period. These conclusions are apparently substantiated by a resurvey made during the 1926–27 school session. Therefore, it becomes a matter of importance to determine, if possible, what were the factors involved in the changes. However, before proceeding to the consideration of the probable causes for the improvement in the goiter situation, it may be of interest to discuss briefly the purpose and value of resurveys, incidentally citing instances in which such investigations have been undertaken.

The purpose and value of resurveys.—Just as a primary thyroid survey is valuable in indicating the extent to which endemic goiter prevails in a given community, so does a reexamination of the same group indicate the extent to which prophylactic endeavor has proved successful. A reexamination of thyroids also accomplishes other useful purposes, among which may be mentioned the determination of the results of goiter treatment and the extent to which thyroid enlargement disappears spontaneously.

Resurveys, however, are seldom made, and if they are made, usually fail to find their way into the literature. Yet, it is obvious that the real effect of goiter prophylaxis can not be ascertained without a carefully planned check up. Among the conspicuous resurveys, attesting the value of iodine prophylaxis, were those of Marine and Kimball in Akron, Ohio. Four annual examinations of the same girls showed a decrease in the size of many existing enlargements and maintenance of thyroid equilibrium among normal individuals.

In Rochester, N. Y., resurveys have followed iodization of the water supply. Apparently endemic thyroid enlargements were reduced in number after the institution of this procedure, though other prophylactics were undoubtedly used at the same time. The failure to record the total number of examinations made in each survey casts doubt upon the validity of the conclusion that goiter incidence was reduced. Moreover, no attempt appears to have been made to determine the possible coincident effect of other iodine-containing prophylactics which may have been used. Resurveys are also available from Lorain, Ohio, and Aroostook County, Me., though no significant changes are recorded.

Provided goiter surveys are made by the same observers, under similar conditions, the resulting information serves to indicate changes, or lack of changes, which either have come about naturally or followed definitely planned prophylaxis. While the desirability of thyroid examinations is obvious, it may be pointed out that the best results will accrue when the examiners possess a reasonable amount of skill, training, and experience. Especially are these qualifications essential when it is recalled that the dividing line between the normal and abnormal thyroid gland is not definite and that classification of thyroid size is entirely arbitrary.

Findings during first Cincinnati survey.—During the 1923–24 school session a thyroid survey was made of 47,493 children in the elementary schools of Cincinnati, Ohio.[1] The purpose of this survey was twofold; first, to determine the incidence of endemic goiter; and, second, to make appropriate recommendations for dealing with the conditions discovered.

Examination of 23,710 boys during the first Cincinnati survey disclosed an incidence of thyroid enlargements of all degrees amounting to 26.6 per cent. Among 23,783 girls the percentage was higher, 39.8 per cent. It was particularly noted that a considerable number of goiters of moderate and marked size were present among those examined. As a result of the findings it was recommended to the board of health of Cincinnati that the general use of iodized table salt be advocated for the prevention of simple thyroid enlargement. Following this recommendation iodized salt was used to a considerable extent in the city. The Cincinnati Academy of Medicine withheld its official sanction of this prophylactic, but did not go on record against it.

Methods employed and scope of the 1927 survey.—The method of examining and the classification of enlargements noted during the 1927 survey was identical with the procedure adopted in 1924. The conduct of the thyroid survey has been presented in several service publications.[1, 2]. In 1924 the examinations were made by the writer in conjunction with the district physicians of the board of health, all of whom had been carefully schooled in uniform procedure. In 1927 the examinations were made exclusively by two examiners, the writer being assisted by Acting Assistant Surgeon Neil E. Taylor, who had already had two years of experience with the original method of examination.

In 1924 the thyroid survey included the children in 61 elementary public and 43 elementary parochial schools. In 1927 fewer children, 12,722 boys and 12,818 girls, were examined, but 5 high schools,

1 Robert Olesen: Thyroid survey of 47,493 elementary school children in Cincinnati. Pub. Health Rep., vol. 39, No. 30, pp 1777–1802 (July 25, 1924). (Reprint No. 941.)

2 Robert Olesen: Endemic goiter in Colorado. Pub. Health Rep, vol 40, No. 1, pp. 1-23 (Jan. 1, 1925). (Reprint No 983.)

as well as 31 elementary public and 4 elementary parochial schools, were included. The schools included in the 1927 survey, while fewer in number than in 1924, were equally representative of location, environment, economic condition and other factors likely to exert an influence upon thyroid status.

RESULTS OF 1927 SURVEY

Age incidence of goiter.—Among the 12,722 boys surveyed in 1927 there were 2,859 boys having enlargements of all degrees, a percentage of 22.5. Among the girls, on the other hand, there were 5,026 having enlargements, a percentage of 39.2. The numbers and percentages of children having thyroid enlargement have been set forth in Table 1, according to age, sex, and color. The percentage incidence of simple goiter at each age among the boys is shown in Chart 1. In the same chart is displayed the incidence among the

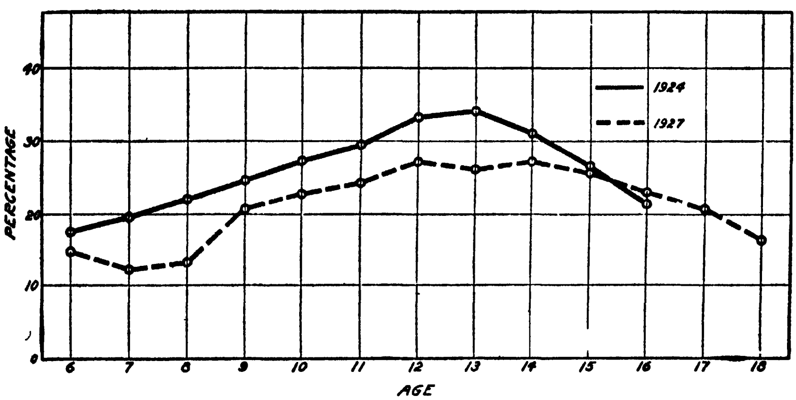

CHART 1.—Comparison of age incidence of endemic thyroid enlargement among 23,710 boys examined in 1924 and 12,722 boys examined in 1927 in Cincinnati

boys examined in 1924. A similar graphic representation for the girls of each age is presented in Chart 2. In these charts it will be noted that there is a gradual though steady increase in the incidence of thyroid enlargement among boys, beginning at the age of 6 and reaching a peak between 12 and 14 years. Thereafter there is a similarly gradual decrease in thyroid involvement until the age of 18 is reached. Among the girls the increase in percentage incidence of thyroid enlargement is steady from 6 to 16 years of age.

Incidence of various degrees of thyroid enlargement.—That the vast majority of enlargements present in both sexes were very slight in character is indicated in Table 2. Ninety-four and five-tenths per cent of the boys and $78\frac{5}{10}$ per cent of the girls having enlargements were so classified. Slight enlargements were present to the extent of 5 per cent among the boys and 16.8 per cent among the girls having enlargements. Contrary to the findings in the 1924 survey,

there were very few moderate and marked thickenings among the boys examined in 1927. There were also fewer of the larger goiters among the girls, 2.1 per cent of the girls with enlargements being classed as having moderate and 0.28 per cent as having marked enlargements. Among the 2,859 boys with some degree of thyroid enlargement, 67 or 2.3 per cent were presumably adenomatous in character. There were 314 or 6.2 per cent of adenomatous glands among the 5,026 girls with enlargements. The numbers, degrees, and percentages of endemic thyroid enlargement among the boys and girls at each age period are shown in Table 3.

COMPARISON OF 1924 AND 1927 FINDINGS

When a comparison is made of the results of the 1924 and 1927 thyroid surveys, some interesting observations are possible. In the

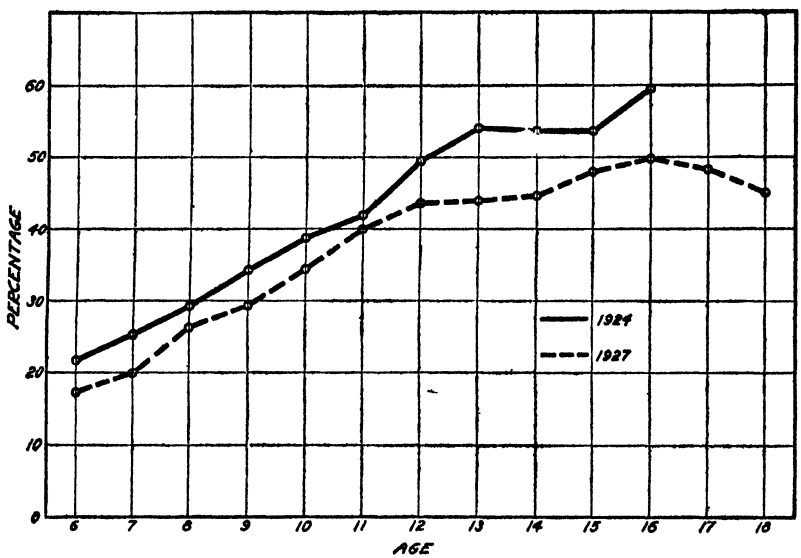

CHART 2.—Comparison of age incidence of endemic thyroid enlargement among 23,783 girls examined in 1924 and 12,818 girls examined in 1927 in Cincinnati

aggregate, the incidence of endemic thyroid enlargement differs little in the two surveys. Thus, the total percentage of thyroid enlargement among the boys in 1924 was 26.6, and it was 22.5 in 1927; among the girls 39.8 in 1924 and 39.3 in 1927.

Inasmuch as the aggregate rates were approximately the same in the two surveys, it becomes necessary to institute a careful study in order to detect evidence of changes that may have occurred in the three-year interval. In chart 1 the curves showing the incidence of endemic thyroid enlargement among the boys examined in 1924 and 1927 are presented graphically. Similar curves for the girls are shown in chart 2. A study of the curves in these charts shows

uniform trends for each sex and a lessened incidence at each age in 1927. The apparent discrepancy between the approximately similar total incidence rates and the interval between the age incidence can probably be explained by the inclusion of the 17 and 18 year age groups in the 1927 survey.

Differences in degrees of thyroid enlargement.—The percentages of each degree of thyroid enlargement encountered during the 1924 and 1927 surveys are set forth in Table 3. These data are shown graphically in chart 3. It will be seen that more very slight thyroid enlargements were recorded in 1927 than in 1924, the excess being more marked among the girls. However, among the other degrees of enlargement there were marked reductions in the percentages noted in 1927 when compared with the findings of the earlier survey.

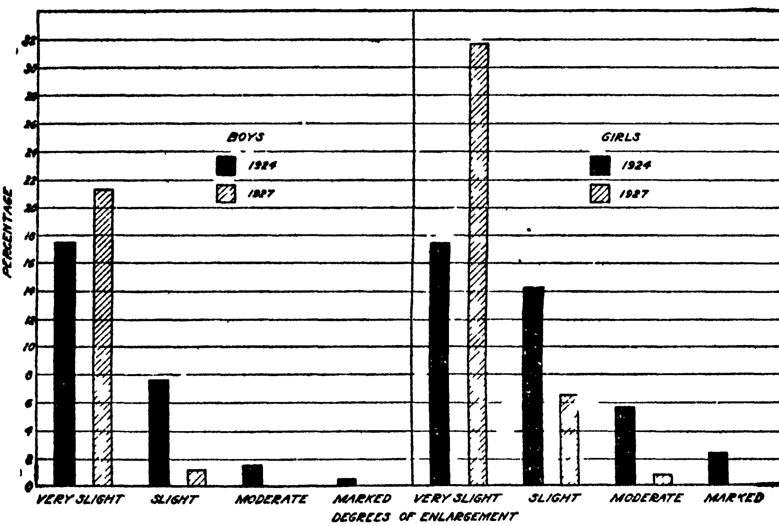

CHART 3.—Comparison of degrees of endemic thyroid enlargement among 23,710 boys and 23,783 girls examined in 1924 and 12,722 boys and 12,818 girls examined in 1927 in Cincinnati

In fact, moderate and marked thickenings were comparatively infrequent among the girls and rare among the boys examined in 1927.

A point of considerable interest in connection with the resurvey in 1927 was the increased incidence of simple thyroid enlargement among the colored girls. Repeated inquiry has elicited the information that relatively few colored children receive either prophylaxis or treatment for goiter. Then, too, it is known, as a result of studies made in Cincinnati, that the natural incidence of simple goiter is greater among colored children, and particularly among the girls.

CAUSES OF CHANGES OCCURRING BETWEEN THE TWO SURVEYS

The same children examined in both surveys.—The children included in the 1927 survey were, with minor exceptions due to the extensive

turnover peculiar to a large city, those examined in 1924. The children attending the first, second, and third grades in 1927 were not, of course, examined in 1924 because they were not in school at that time. However, those attending the sixth, seventh, and eighth grades in 1924 were again examined in 1927 by including the high schools, to which many of them had in the meantime advanced. In view of these facts, it may be concluded that the children examined in the two surveys were, with minor exceptions difficult of control, the same.

Reasons for changes in goiter incidence.—In seeking for an explanation of the reduction in the general incidence of goiter and the marked decrease in the number of thyroid enlargements of considerable size, a number of factors deserve consideration. Among these may be mentioned changes in methods of examining, altered standards of recording, and changes in the personnel engaged in making the examinations. The possibility of spontaneous disappearance or natural reduction in size of thyroid enalrgements must likewise receive a share of attention. Furthermore, the influence of prophylaxis and treatment also enters into the problem.

Variations in estimates of thyroid involvement.—As previously indicated, the writer supervised and actively participated in both surveys, coaching the other examiners in uniform methods of examining and classifying the thyroids. Consequently the results of the surveys may be regarded as comparable. As additional experience and skill in palpating the thyroid gland are gained there may be a tendency, unconsciously, to revise the arbitrary standards for classifying enlargements. An effort was made to prevent such errors from creeping into the work. As a matter of fact, it is believed that the thyroid enlargements were more sharply classified in 1927 than during the earlier investigation. All things considered, it is believed that no detectable changes in methods occurred which might distort the comparative figures. To some extent this contention is borne out by the similarity of trends, as indicated in charts 2 and 3.

Spontaneous reduction in thyroid enlargement.—It is well known that many endemic goiters tend to disappear spontaneously as children grow older. This tendency is particularly marked among boys after the age of 12 or 13 years. As to the factors involved in the voluntary subsidence of thyroid swelling, little is known beyond the fact that it does occur. However, it is not felt that spontaneous resolution of thyroid involvement accounts either for the decrease in goiter incidence or the reduction in size of existing enlargements noted between the two surveys.

Decrease in number of larger goiters.—The marked decrease in the number of goiters of considerable size is probably due to the action taken in behalf of many children who, in 1924, were found to have such enlargements. The results of the 1924 goiter survey were

afforded much publicity. Consequently many children received treatment from their family physicians. That such treatment was successful to a large extent is attested by the reduction in the sizes of many goiters. Credit must also be given the nurses of the Cincinnati Health Department, who "followed up" the children having moderate or marked thyroid enlargements and saw that appropriate medical treatment was secured. That goiter of marked size became less frequent in occurrence after the 1924 survey in Cincinnati was a fact noted by many lay observers, particularly school teachers, whose close contact with the children enabled them to see the changes.

Influence of prophylaxis.—Following the announcement that endemic goiter prevailed to a considerable extent in Cincinnati prophylactic measures were advocated and widely practiced. In addition to the rather general use of iodized table salt, various other iodine prophylactics were obtained by many children from their family physicians. The reduction in goiter incidence, though comparatively slight, suggested the possibility that iodized salt, the principal prophylactic recommended, may have had a share in the inprovement. However, as other preparations were undoubtedly used at the same time, it can not be asserted that iodized salt played the sole or principal rôle.

It is also difficult to estimate the influence of iodized salt or other prophylactics upon existing enlargements. Ordinarily it is doubtful whether iodine in prophylactic doses assists in reducing thyroid enlargements. However, in the present instance it may be surmised that iodized table salt and other iodine-containing preparations aided to some extent in reducing the size of the goiters. Further observations of more extensive and accurate character are manifestly required before a conclusion can be reached.

SUMMARY

1. A resurvey of endemic thyroid enlargement in Cincinnati, Ohio, in 1927, three years after the original thyroid survey, showed a lessened incidence of the disease and a considerable reduction in the number of goiters of moderate and marked degree.

2. The aggregate incidence of endemic goiter in 1927 was only slightly less than in 1924 but the age incidence was distinctly less in 1927. While iodized table salt was the chief prophylactic recommended and used, it is known that other iodine-containing preparations were also used. It may be surmised that iodized salt was a factor in the slight reduction of goiter revealed by the 1927 survey.

3. There was a notable decrease in the thyroid enlargements of considerable size noted in 1924 and again in 1927. This was due largely to efficient treatment instituted by physicians at the instigation of parents. It is possible that iodized salt and other prophylactics may also have exerted a favorable influence.

LEAD POISONING FROM THE USE OF SNUFF

A case of lead poisoning traced to the use of snuff adulterated by the addition of coloring materials containing lead, was reported in the Weekly Bulletin for November 5, 1927, issued by the New York City Department of Health. Attention is also called to the fact that snuff may be adulterated by lead pigments either for coloring purposes or to give spurious weight. The case reported is of clinical interest in showing the alertness that is sometimes necessary in discovering the cause of such poisoning. The following is taken from the Weekly Bulletin:

"One of the medical staff of Mount Sinai Hospital recently called the attention of the department of health to a male patient, who,

upon examination, presented a marked polyneuritic condition that was suggestive of poisoning by one of the heavy metals. Lead was suspected, and the only possible etiological factor in this case was thought to be snuff, which the patient habitually used. The patient's stool contained lead, and an examination of the specimen of the snuff used by the patient in the chemical laboratory of the department of health showed lead present.

"Investigation by the bureau of food and drugs, at the plant where the snuff used by this patient was manufactured, proved conclusively that the lead content of the snuff was due to the use of a yellow and green coloring material. When the analysis of the chemical laboratory indicated the source of the lead content, an embargo was placed on all coloring materials in the plant, and the manufacturer was ordered to discontinue the use of all coloring matter at once. Prosecution proceedings have been instituted against the manufacturer."

DEATH RATES IN A GROUP OF INSURED PERSONS

Rates for Principal Causes for November, 1927

The death rate for November among approximately 18,000,000 industrial policyholders in the United States and Canada was 8.5 per 1,000, according to the Statistical Bulletin for December, published by the Metropolitan Life Insurance Co. This is the same rate as that for November of last year for this group of persons.

Death rates (annual basis) for principal causes per 100,000 lives exposed, November 1927, as compared with October and with November, 1926

Cause of death	Rate per 100,000 lives exposed [1]			
	Nov. 1927	Oct. 1927	Nov. 1926	Year 1926
Total, all causes	849.8	769.7	850.2	945.6
Typhoid fever	4.3	3.7	6.2	4.2
Measles	1.0	.4	1.2	10.2
Scarlet fever	2.6	1.5	3.2	3.4
Whooping cough	3.9	4.1	6.1	9.6
Diphtheria	12.4	9.6	12.9	9.7
Influenza	11.0	6.5	13.5	31.1
Tuberculosis (all forms)	79.2	74.7	85.9	99.0
Tuberculosis of respiratory system	70.3	66.5	76.4	86.7
Cancer	73.5	71.6	72.2	73.7
Diabetes mellitus	16.2	15.0	16.1	16.7
Cerebral hemorrhage	53.2	49.0	50.6	55.6
Organic diseases of heart	135.2	112.0	125.5	134.8
Pneumonia (all forms)	66.0	46.3	71.6	98.2
Other respiratory diseases	14.9	12.6	11.8	13.0
Diarrhea and enteritis	23.1	36.6	27.7	29.8
Bright's disease (chronic nephritis)	66.7	60.5	70.5	73.5
Puerperal state	14.5	12.6	11.1	15.3
Suicides	8.0	7.4	8.0	7.7
Homicides	7.6	6.8	7.3	7.0
Other external causes (excluding suicides and homicides)	62.4	62.4	62.6	62.3
Traumatism by automobiles	20.8	20.3	19.8	16.8
All other causes	194.2	176.4	186.1	191.0

[1] All figures include infants insured under 1 year of age.

The mortality rates for the principal causes of death of major public health interest were lower than those prevailing last year, with the single exception of the rate for puerperal causes.

The mortality from organic heart disease was 7.7 per cent higher in November than it was a year ago. The rates for cancer and cerebral hemorrhage were also a little higher, while the death rate for Bright's disease was lower.

COURT DECISIONS RELATING TO PUBLIC HEALTH

Liability of town for antirabic treatment.—(Massachusetts Supreme Judicial Court; Bryant *v.* Nolin et al., 158 N. E. 791; decided November 23, 1927.) The chairman of a town board of health requested the town physician to "look into the case" of a boy who had been bitten by a rabid dog. The boy's parents permitted antirabic treatment to be given, but with the expectation that the town would pay for same. "Rabies" and "dog bite requiring antirabic treatment" were diseases defined by the State department of public health as dangerous to the public health. In an action brought by the physician against the parents to recover for medical services rendered the child, the supreme court upheld the action of the trial court in directing a verdict for the defendants, saying:

> The order was clearly right. There was no express contract, and no contract was implied in fact or in law, to pay the plaintiff for the services rendered in the circumstances disclosed. Assuming the physician rendered services outside the terms of his employment as town physician to the board of health, and further assuming that such services were reasonably required by the board of health in making the provisions required by law for persons infected with a disease dangerous to the public health, the town was obligated to pay to the plaintiff the reasonable value of the services rendered at the request or at the direction of the board of health, and had a remedy over against the defendant[s] if they were able to pay. (G. L. c. 111, sec. 116; Haverhill *v.* Marlborough, 187 Mass. 150, 72 N. E. 943.)

Town held liable for sewage pollution of stream.—(Iowa Supreme Court; Stovern *v.* Town of Calmar, Winneshiek County, 216 N. W. 112; decided November 22, 1927.) An action was brought against a town for an injunction and damages on account of the pollution by sewage of a creek which flowed through the edge of plaintiff's farm. At the time of the trial in the lower court in October, 1926, the town had a sanitary sewage disposal plant about three-fourths completed. The trial court allowed the plaintiff damages, refused an injunction, and ordered the nuisance abated on or before January 1, 1927. Both parties appealed. The supreme court approved the amount allowed as damages by the trial court, but held that the latter court "should not have made its decree final, but the same should have been in its nature interlocutory, giving the defendant a reasonable time in which to abate the nuisance, but holding jurisdiction for the final determina-

tion herein as to the rights of the parties in this respect." The supreme court stated that it did not know whether the nuisance had been abated and remanded the case to the district court "for the purpose of taking evidence upon the single proposition as to whether a nuisance still exists, and for the purpose, that, upon said hearing, such decree with reference thereto as may be warranted by the evidence may be rendered."

Ordinance for prevention of pollution of source of city's water supply, located in United States forest reservation, held invalid.—(Washington Supreme Court; Brown *v.* City of Cle Elum, 261 P. 112; decided November 23, 1927.) The city of Cle Elum, under contract with the United States, took its water supply from a lake outside the city and within the limits of a United States forest reservation. The city, pursuant to statutory authority, passed an ordinance designed to prevent the pollution of the source of its water supply. This ordinance, among other things, prohibited swimming, fishing, and boating in the said lake. The United States had rented cottage sites along part of the lake, and the plaintiff in this case was a tenant of the United States. He sought to restrain the defendant city from enforcing or attempting to enforce the ordinance, particularly in so far as it prohibited or attempted to prohibit swimming, fishing, or boating in the lake. The validity of the ordinance was attacked on two grounds: (1) That its enactment was an attempted exercise of the police power of the city over lands and waters owned by the United States, and (2) that it was unreasonable. The case was heard before department 2 of the supreme court, and on April 28, 1927, a decision (255 P. 961) was rendered in favor of the city. Upon a reargument of the case before the court en banc the question was presented to the court as to whether or not the legislature could constitutionally delegate to a city authority to exercise police power beyond its territorial limits and outside the boundaries of property it may own beyond its territorial limits by the passing and enforcing of ordinances assuming to regulate the conduct of citizens beyond such limits and boundaries. The State constitution provided:

> Any county, city, town, or township may make and enforce within its limits all such local, police, sanitary, and other regulations as are not in conflict with general laws.

The court then held that, in view of this provision, those statutory provisions, which purported to give to the city the power to pass such an ordinance as the one involved in the instant case, could have no validity. The court said:

> This delegation of its police power by the State to various municipalities is strictly limited to the exercise of that power *within the limits* of such municipalities. Authorities are cited to the effect that the State, by legislative enactment, might delegate its police power to various municipalities to be exercised beyond

their limits, but those authorities will be found to have not arisen where a constitutional provision obtains such as the one existing in this State. In order for the appellant in this case to pass a valid ordinance under the sections of the code relied on, it would be necessary for the court to read out of the constitutional provision the words, "*within its limits*," and no case has been cited to us, and we have been unable to find one, where legislation similar to that here under consideration has been sustained where there also existed a constitutional provision such as ours. * * *

THE EIGHTH PAN AMERICAN SANITARY CONFERENCE—RESOLUTIONS—CORRECTION

In the report of the resolutions adopted at the Eighth Pan American Sanitary Conference, published in Public Health Reports for January 6, 1928, the word "maritime" was omitted before the last word, "travel," in paragraph (*b*), page 9. The concluding part of this paragraph should read, "during the time in which he is not engaged in maritime travel."

PUBLIC HEALTH ENGINEERING ABSTRACTS

Distribution and Succession of Protozoa in Imhoff Tanks. James B. Lackey. Report of sewage substation of the New Jersey Agricultural Experiment Station for year ending June 30, 1926, pp. 506-520.

A study to determine how and why protozoa are distributed throughout the depth of Imhoff tanks. Six diagrams and three tables present numerical data.

"(1) Flagellates are far more numerous than ciliates in Imhoff tanks; (2) vertically, flagellates are present in maximum numbers usually between 5 and 7 feet; (3) there is no definitely located point for the ciliate maximum; it varies greatly; (4) there is as yet no proof of a well-defined seasonal succession for any of the protozoa; (5) tanks which are not foaming have relatively small protozoan populations; (6) the numbers of protozoa decrease to the point of defaunation in tanks which are shut off; conversely, they increase enormously if a tank runs indefinitely; (7) their numbers are independent of observed ranges of pH and temperature in the tanks; (8) they are largely saprophytic forms, so a continuously running tank offers a constant food supply for them; (9) there is an absolute correlation between large increases in their numbers and foaming; (10) no definite explanation is at hand for the part they play in foaming."

But an increase in protozoa marks a danger point for the tank, and "if their increase be noted, the tank should be shut off or, better, corrected with lime."

English View of Sewage Disposal. Anon. *Public Works*, vol. 58, No. 10, October, 1927, pp. 400–402. (Abstract by W. J. Downer.)

Compares present status of dilution, irrigation, contact beds, percolating filters, activated sludge, tank treatment, and sludge disposal. Operation and advantages of each are briefly described.

Activated sludge treated more fully. Dilution is an authenticated method when sewage volume is reasonably apportioned to volume of diluent, salt or fresh. The Royal Commission has stated that 1 cubic yard of medium used in form of percolating filters is capable of performing same duty as 2 cubic yards of medium used in form of contact beds. Lagooning has taken the place of

pressing in English practice to a large extent and is far from ideal as regards smell nuisance.

Research on the Composition of the Gray Slimy Growth on the Surface of Sewage Filters. H. D. Bell. (*Surveyor*, 1926, v. 70, 561–565. Abstract by W. Rushton in the *Bulletin of Hygiene*, vol. 2, No. 7, July, 1927, pp. 546–547.

"The author describes attempts to isolate the various mixed growths of organisms which make up the flora of the gray slime of sewage filters and to investigate their relationships to the insect *Achorutus viaticus*.

"By the use of dilute solutions of copper sulphate and formalin it was found that two types of fungi and two types of bacteria were the principal living forms, namely: *Oidium lactis*, a mold; *Torula rosea*, a pink wild yeast; *Bacillus subtilis* and *Bacillus coli communis*.

"In 1922 a slimy growth was found on the walls of a cellar in which food, beer, etc., had been stored, and thriving on this growth types of the insect *Achorutus viaticus* were found. In general appearance this growth resembled the sewage filter growths except in color.

"Isolation of the growths showed—

Slimy growths from Barnsley sewage	Slimy growths from Ripon cellar
Torula rosea (wild yeast).	*Torula rosea.*
Mucor mucedo (mold).	*Mucor rouxii* (mold).
Oidium lactis (mold).	*Oidium lactis.*
Penicillium (mold).	*Penicillium glaucum* (mold).
Bacillus coli communis.	

"The growth from the Ripon cellar had no contact with sewage, yet it contained two organisms in common with sewage, viz, *Oidium lactis* and *Torula rosea.*

"The molds produce hyphal threads and spores, and *Torula rosea* has a somewhat similar structure in media containing carbohydrates.

"As *Schorutus viaticus* thrived equally well on both sewage and cellar growths it would appear that their food was the filamentous structures of the molds *O. lactis* and *Mucor* and *Penicillium.*

"The author suggests a theory as to the formation of the gray slimy growths, showing how the sticky fluid having attached a mold to a piece of solid matter such as filter media, offers a surface upon which another film of tank effluent may rest, and so accelerate the production of more molds from spores, thus forming a network of molds which prevents free aeration, and encourages anærobic growths, causing the surface to become foul. This is what is known as the beginning of clogging. As *Achorutus viaticus* is unable to live under the surface of a liquor, nor in the absence of air, it must either attack the molds or the slimy growths formed below, and prevent the formation of spores, or it must walk on the surface of the liquor and attack the hyphal threads with attached spores. Probably it does both, and in doing so aids in opening up the filter surface, thus restarting the free circulation of air by which the oxidizing and nitrifying organisms can propagate at a greater rate.

"The effect of this action is borne out by the increase of nitric nitrogen and suspended matter from a filter after colonization by *Achorutus.*

"If this theory is correct, it explains why a sewage filter is kept clean by means of the insect named, and also why a sewage filter will eventually 'pond,' even in the presence of the insect if an excessive amount of tank effluent is sprayed on the filter without suitable resting periods.

"Proof of the food of the insect was demonstrated by feeding it on pure cultures of the molds *O. lactis*, *M. mucedo*, *M. rouxii* and *Penicillium*, when it was seen that it lives at the expense of the mycelium of the molds.

"Since the author published his paper on The Maintenance of Clean Filtering Media on Sewage Filters (Assn. Managers Sewage Disposal, Leeds, Nov. 12, 1921) he has sent boxes of media containing eggs of the insect to nearly 40 sewage installations, including many abroad, some of which had to withstand tropical conditions and others extreme cold. On nearly 20 sewage installations in this country the insect has appeared naturally, and on these works ponding has scarcely been seen; this is attributed to its activities.

"The author desires information from sewage-disposal works where the insect is present naturally or introduced, (*a*) whether the insects are doing good work, (*b*) whether they appeared naturally or were introduced, (*c*) whether their colonization has been attempted and found successful.

"In conclusion, the author affirms that the interlacing hyphæ of *O. lactis*, the *Mucors* and probably other fungi is the probable origin of the gray, slimy growth of sewage filters, that the insect *Achorutus viaticus* feeds on it, and that neither copper sulphate 1–50,000 nor formalin 1–100,000 sprayed on the surface will prevent the formation of the gray, slimy growths on filters where the insect named has failed to colonize.

"In discussion, some speakers confirmed in all respects the usefulness of *Achorutus;* one pointed out that the winter period is the time when the slimy deposits are most prolific, suggesting a temperature factor. Others associated the slimy growth rather with bacterial activity than fungal, i. e., a bacterial factor as the dominant one. Attention was drawn to the Report of the Royal Commission on Sewage Disposal, where some of the workers tried various chemical ingredients, such as quicklime, chloros, and reported that caustic soda removed the growths.

"In reply the author stated his investigations had been confined to two or three works where the trade wastes had not been large, and it was possible other growths might appear at other sewage works."

Digestion of Activated Sludge. W. Rudolfs and P. J. A. Zellar. *Public Works*, vol. 18, No. 7, July, 1927, pp. 253–255. (Abstract by H. H. Hasson.)

This article is a summary of experiments on the effect of seeding activated sludge with ripe Imhoff sludge, mixing ripe sludge and fresh solids with it in proportion to secure most rapid digestion, and the effect of reaction control on digestion. Mixtures of ripe sludge and fresh solids, ripe sludge, fresh solids and activated sludge, ripe sludge and activated sludge, and activated sludge alone were used. Regular analyses (detailed description of method to be published later) of solids and ash and pH determinations were made. Bacterial and protozoan numbers were obtained and gas production of all materials was measured and analyzed.

The conclusions reached were that the activated sludge digests most rapidly when seeded with proper amounts of ripe sludge; that properly seeded activated sludge digests more rapidly and with less odors than properly seeded fresh solids; and that if gasification be desired properly seeded activated sludge should be treated with hydrated lime to a pH value of 7.5 to 7.6 (when necessary).

Effect of Lime on Sludge Digestion. W. Rudolfs, H. Heukelekian, P. J. A. Zeller, D. Peterson, J. R. Downes. Report of the Sewage Substation of the New Jersey Agricultural Experiment Station, year ending June 30, 1926, pp. 412–498. (Abstract by W. M. Olson.)

Presents detailed results of exhaustive research to determine the effect of lime under different conditions prevailing during digestion. Thirty-eight figures show 230 series of observed relations. Thirteen tables of data are given.

The report describes experiments with a series of bottles in the laboratory, with three Imhoff tanks in operation and at rest, and with a separate sludge-digestion tank. In each case methods and results (chemical, bacteriological, and zoological) are stated, followed by a discussion and summary. The amounts of lime necessary for the adjustment of fresh solids and other material in digestion tanks are discussed at some length, previous to the concluding general discussion of the study as a whole.

The laboratory work showed that lime has a pronounced effect upon sludge digestion, influencing the flora and fauna and consequently the chemical intermediate and end products. "Most rapid and satisfactory digestion proceeds at pH values of 7.3 to 7.8. If the reaction of incoming fresh solids is kept at pH 7.3 to 7.6, odors are practically absent." In a previous report (*American Journal of Public Health,* 16: 365–368) it was stated that digestion takes a normal course when two parts of dry fresh solids are added daily to 98 parts of ripe sludge (dry basis). With the use of lime to adjust the pH values of incoming fresh solids to 7.3 to 7.6, the above mentioned ratio may be increased from 2.0 to 3.5 or possibly 5 per cent, reducing greatly the volume of ripe sludge necessary for efficient digestion. Using the ratio of 2 parts fresh solids to 98 parts ripe sludge, "unadjusted but properly seeded material requires a per capita digestion space (in summer) of not less than 2.6 to 2.7 cubic feet. With reaction control * * * this * * * capacity can be reduced to 1.4 to 1.5 cubic feet."

In the plant experiments, "A comparison of two Imhoff tanks, one treated with lime to adjust the reaction of its contents, and the other untreated, showed that the treated tank gave no sign of foaming and was free from scum for several months in spite of the fact that it was continuously operating, whereas the untreated tank had to rest and could not be put into operation for a long time on account of heavy foaming."

On account of special conditions prevailing at the treatment plant it was not possible to carry the experiments on the separate sludge-digestion tank far enough to determine the maximum load which the tank could handle. With reaction control and the application of heat toward the end of the test, the tank provided satisfactory digestion in winter of 2.3 per cent fresh solids (dry basis) daily. The practicability of maintaining a comparatively high temperature in a sludge-digestion tank was demonstrated. The separate sludge-digestion tank did as well as a good working Imhoff tank. "Whether Imhoff tanks or separate sludge-digestion tanks are to be used depends upon the cost (construction and operating) and upon their flexibility and their ease of control." The control of the reaction of the contents and of the daily addition of definite quantities of fresh solids is simpler in separate sludge-digestion tanks than in Imhoff tanks. Likewise it is easier to heat a separate sludge-digestion tank.

"Figures and curves are presented to show the amounts of lime necessary to adjust the reaction of incoming fresh solids of different concentration. Examples are given for correction of poorly working, acid tanks. The reasons for adjustment are briefly discussed. Lime, if needed, should be added daily * * *. Examples of adjustment and methods of application of lime are given. The amount of lime necessary to adjust Plainfield fresh sewage solids to pH 7.3 is from 3 to 4 pounds per million gallons sewage daily; to adjust them to a pH value of 7.6 about 25 pounds per million gallons daily. * * * Good results in the correction of an Imhoff tank were obtained by adding dry hydrated lime to the digestion compartment with the aid of a small pump * * *. Material was pumped out of one compartment into the other and lime added. * * * With increased hardness of water the rate of sludge digestion should increase."

"Summarizing the discussion on the effect of lime on digestion we can state that probably several factors are of more or less importance: (a) Its effect on the activities of microorganism; (b) chemical reactions induced; (c) cause of change in physical conditions of digesting material.

"The effect on the activities of microorganisms may be: (1) Making the medium more favorable for acid producing organisms; (2) inducing the establishment of a predominantly different flora; (3) making the medium less (or more) favorable for protozoa.

"Chemically it affects the organic and mineral acids and under certain circumstances favors the liberation of ammonia.

"Physically it flocculates the finely divided materials (hydrophyllic colloids) changing the viscosity and affects the surface tension of the liquid."

Bushy, Hertz, Sewerage and Sewage Disposal. Anon. *Surveyor*, vol. 72, No. 1867, November 4, 1927, p. 406. (Abstract by J. B. Harrington.)

This is a brief article describing the sewage-disposal plant for the urban district of Bushy, present population 12,743. All sewage, with the exception of a small area flows by gravity to the purification works located on a 31½-acre tract of land in the district of Watford.

Previous treatment of sewage consisted of chemical precipitation and downward filtration through 5 acres of land. Unsatisfactory results by this method were responsible for the construction in 1910 of a more modern plant comprising the following units: Duplicate grit and screening chambers, two sedimentation tanks 28 feet in diameter by 14 feet deep, four rectangular sedimentation tanks 40½ by 35 by 4½ feet, one dosing chamber with two automatic siphons, two sludge tanks 17½ by 15 by 15 feet, five trickling filters 90 feet in diameter by 5 feet deep, six sand filters, combined area 2,300 square yards, and two rectangular storm-water tanks 80 by 22 feet by 2 feet 9 inches.

Increased population made it necessary to provide the following minor changes: Two new grit and screening chambers, remodeling of one circular sedimentation tank, construction of an octagonal humus tank 25 feet in diameter by 24 feet 2 inches deep, between the trickling filters and sand filters, and three new sludge digestion tanks and five sludge drying beds.

The construction of the supplementary units makes it possible to deliver practically an odorless effluent and sludge.

Production of Illuminating Gas from the Stuttgart Sewage Filter Plant. W. Sohler, *Gas. u. Wasserfach*, 70, 945–9 (1927). Abstract by R. W. Ryan in *Chemical Abstracts*, vol. 21, No. 22, Part I, November 20, 1927, p. 4000.

"A daily gas production of 3,000 to 4,000 cubic meters of gas is obtained from the anærobic fermentation of sludge from the Stuttgart sewage (population of Stuttgart, 350,000). The gas analyzes about 12 to 20 per cent CO_2, 4.8 per cent H_2, 75.5 per cent CH_4, and 4.7 per cent N_2, and has a calorific value of 7,500 to 8,500 cal. per cu. m. The method of recovery of this gas is described and illustrated. The gas is sold to the Gaisburg gas works."

The Aluminate-Alum Coagulation of Water. C. H. Christman. Bulletin 18–A, issued by the Chicago Chemical Co. 6 pages. (Abstract by W. A. Hardenbergh.)

Alum has been used almost universally as a coagulent in water purification, but its use with certain waters or under certain conditions has not been satisfactory. In some waters in the Great Lakes region, 0.2 to 0.4 grains per gallon is an efficient dose, but some plants in other sections require as much as 5 or 6 grains per gallon. Studies of these phenomena have shown that colloidal waters do not yield readily to treatment by alum. The application of hydrogen-ion

control resulted in great advances, but the principles of colloid chemistry, it is felt, will yield still further advances.

Many workers have sought a coagulant that would meet the conditions required by their water supply, and also yield an effluent of sufficient alkalinity to be noncorrosive. Sodium aluminate therefore came into use, but was not entirely satisfactory, until a certain type of the chemical, itself possessing colloidal properties, was used. Further research is now going on. An account of the results at several plants is given.

Ueber die Abwasserreinigung mit Aktiviertem Schlamm Nach Versuchen mit Muenchener Kanalwasser. (Experiments with activated sludge, etc.) M. Strell. *Gesundheits-Ingenieur.* 1927, vol. 50, pp. 179–182. Abstract by M. E. Delafield in the *Bulletin of Hygiene*, vol. 2, No. 7, July, 1927, pp. 549–550.

"This is in the main a description of certain experiments with the activated sludge process. It is maintained that the mode of action is only to a slight extent a physical one and that by far the greatest part is a biological action brought about by bacteria, protozoa, and metazoa. In activated sludge it is possible to demonstrate the existence of such enzymes as diastase, invertase, glycogenase, maltase, lipase, pepsin, trypsin, urease, oxydase, and katalase. The experiments consisted in determining the variation in the purification of crude sewage resulting from varying the time and the amount of aeration, and the proportion of added sludge.

"The general conclusions reached were: (1) That the addition of about one-third of activated sludge was the most effective; (2) that the greatest purification occurred in the first hour and was about 60 to 70 per cent; (3) provided there is sufficient aeration to keep the sludge in movement, further increasing the amount of air does not improve the purification materially; (4) too great an aeration has the effect of breaking up still further the sludge particles and so producing a turbid effluent containing more suspended matter."

Residential Sewage Treatment Plants. Lindon J. Murphy. Bulletin 93, Iowa State College of Agriculture and Mechanic Arts Official Publication, vol. 25, No. 70, May 28, 1927. 23 pages. (Abstract by W. L. Havens.)

This article summarizes the essential design and construction details of house plumbing, grease traps, house sewers, cesspools, Imhoff tanks, septic tanks, subsurface irrigation, trickling filters and intermittent sand filters as applied to sewerage facilities for residences and small communities. Sketches of the various devices are given, together with methods of construction and methods of estimating the costs of the different systems. Basic features of design and general operating suggestions are also given. The article should be of particular interest to those who contemplate the installation of small residential plants and who depend upon a carpenter contractor for engineering advice.

MORTALITY SUMMARY FOR 75 LARGE CITIES, 1927

Number of deaths, death rates, and infant mortality in 75 large cities of the United States for 1927 and comparison with 1926

[From the Weekly Health Index, Bureau of the Census, Department of Commerce]

[1] For the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; and Washington, D. C., 25.

[2] Based upon telegraphic reports received each week from city health officers.

[3] Allowance has been made for the extra day which must be added to the 52 weeks to give a period of 365 days.

[4] Infant mortality rate is based upon deaths under 1 year as returned each week and estimated births, 1927.

[5] Based upon deaths which occurred within the calendar year.

[6] Infant mortality rate for the cities in the birth registration area appearing in the summary.

[7] Mortality rates are omitted, pending the establishment of more satisfactory estimates of population.

[8] Cities with no infant mortality rate are not in the registration area for births.

Number of deaths, death rates, and infant mortality in 75 large cities of the United States for 1927 and comparison with 1926—Continued

[From the Weekly Health Index, Bureau of the Census, Department of Commerce]

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Date for 59 cities.
[4] Date for 66 cities.
[5] Deaths for week ended Friday, Jan. 6, 1928.
[6] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Knoxville, 15; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 97 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 30,500,000. The estimated population of the 93 cities reporting deaths is more than 29,900,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended December 31, 1927, and January 1, 1927 [1]

	1927	1926	Estimated expectancy
Cases reported			
Diphtheria:			
42 States	2,283	1,907	
97 cities	1,096	1,017	1,150
Measles:			
41 States	6,419	6,009	
97 cities	1,846	1,345	
Poliomyelitis:			
42 States	56	17	
Scarlet fever:			
42 States	3,750	4,387	
97 cities	1,229	1,542	1,195
Smallpox:			
42 States	711	675	
97 cities	90	78	68
Typhoid fever:			
42 States	242	312	
97 cities	41	67	47
Deaths reported			
Influenza and pneumonia:			
93 cities	1,013	1,014	
Smallpox:			
93 cities	0	0	

[1] The week ended Jan. 1, 1927, is considered to be the last week of 1926.

City reports for week ended December 31, 1927

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used to as many years as possible, but no year earlier than 1918 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended December 31, 1927, compared with those for a like period ended January 1, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1926 and 1927, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 30,445,000 in 1926 and 30,966,000 in 1927. The 95 cities reporting deaths had nearly 29,785,000 estimated population in 1926 and nearly 30,296,000 in 1927. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, November 27 to December 31, 1927—Annual rates per 100,000 population, compared with rates for the corresponding period of 1926 [1]

FOREIGN AND INSULAR

PLAGUE ON VESSEL

Vessel at La Plata from Rosario, Argentina.—Information dated January 4, 1928, shows the arrival of a case of plague at La Plata on a vessel coming from Rosario, Argentina.

THE FAR EAST

Report for the week ended December 24, 1927.—The following report for the week ended December 24, 1927, was transmitted by the Eastern Bureau of the Health Section of the Secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt.—Alexandria.
Dutch East Indies.—Balik-Papan, Makassar.
India.—Bassein, Rangoon.

CHOLERA

India.—Calcutta, Rangoon.
Straits Settlements.—Singapore.
Siam.—Bangkok.

SMALLPOX

India.—Bombay, Calcutta, Rangoon, Moulmein.
Kwangtung.—Dairen.
Manchuria.—Mukden.

Returns for the week ended December 24 were not received from the following ports:

Aden Protectorate.—Aden, Kamaran, Perim.
Iraq.—Basra.
India.—Madras, Tuticorin.
Ceylon.—Colombo.
Dutch East Indies.—Pontianak.
China.—Canton.
Union of Socialist Soviet Republics.—Vladivostok.

ANGOLA

Communicable diseases—October, 1927.—During the month of October, 1927, communicable diseases were reported in Angola as follows:

October, 1927—Cases

Disease	Coast district	Interior	Land frontier	Total
Ancylostomiasis	13	7		20
Beriberi	2	8		10
Bilharzia	6	2		8

Smallpox				2	12		14
Typhoid fever		48	10	1		1	60

Report from Ontario for week ended Dec. 17, cerebrospinal fever, 1; lethargic encephalitis, 1; smallpox, 104; typhoid fever, 11.

Communicable diseases—Week ended December 31, 1927.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended December 31, 1927, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever				1				1
Influenza	9				3			12
Lethargic encephalitis				1				1
Poliomyelitis				1			1	2
Smallpox				53		13	3	69
Typhoid fever	26	78	7	5	1	1	1	119

Communicable diseases—Quebec—Week ended December 24, 1927.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended December 24, 1927, as follows:

Disease	Cases	Disease	Cases
Chicken pox	47	Scarlet fever	88
Diphtheria	78	Smallpox	14
Influenza	3	Tuberculosis	43
Measles	80	Typhoid fever	10
Poliomyelitis	1	Whooping cough	21

Communicable diseases—Quebec—Week ended December 31, 1927.—The bureau of health of the Province of Quebec reports cases of certain communicable diseases for the week ended December 31, 1927, as follows:

Disease	Cases	Disease	Cases
Chicken pox	61	Smallpox	3
Diphtheria	68	Tuberculosis	23
Influenza	33	Typhoid fever	7
Measles	86	Whooping cough	9
Scarlet fever	74		

Communicable diseases—Ontario—November, 1927—Comparison with corresponding period, year 1926.—During the month of November, 1927, communicable diseases were reported in the Province of Ontario, Canada, as follows:

Disease	November, 1927		November, 1926	
	Cases	Deaths	Cases	Deaths
Cerebrospinal meningitis	1			2
Chancroid	7		1	
Chicken pox	1,080		1,527	
Diphtheria	343	17	393	14
Dysentery		4		
German measles	14		15	
Gonorrhea	170		157	
Influenza		3		7
Lethargic encephalitis	4	1	2	
Measles	542		746	
Mumps	1,007		47	
Pneumonia		74		127
Poliomyelitis	7		8	1
Scarlet fever	402	4	546	
Smallpox	271		95	1
Syphilis	115		99	
Tuberculosis	94	53	84	42
Typhoid fever	59	1	46	5
Whooping cough	285		312	2

Smallpox.—Smallpox was reported present in 21 localities, the greatest prevalence being reported at Ottawa, with 97 cases, Toronto 59, and East York, 51. At eight localities one case each was reported.

CUBA

Communicable diseases—Habana, Cuba—December, 1927.—During the month of December, 1927, communicable diseases were reported in Habana, Cuba, as follows:

Disease	New cases	Deaths	Remaining under treatment Dec. 31, 1927	Disease	New cases	Deaths	Remaining under treatment Dec. 31, 1927
Chicken pox	3	1	1	Measles	9		4
Diphtheria	8	1	4	Paratyphoid fever	1	1	
Leprosy			18	Scarlet fever	4		
Malaria [1]	77		13	Typhoid fever [1]	47	5	44

[1] Many of these cases from the interior.

ECUADOR

Plague—Plague-infected rats—Guayaquil—November, 1927.—During the month of November, 1927, nine cases of plague, with three deaths, were reported at Guayaquil, Ecuador.

During the same period, of 23,240 rats taken at Guayaquil, 6 rats were found plague infected.

Smallpox.—During the period under report one case of smallpox was reported at Guayaquil.

GREAT BRITAIN

Smallpox—Newcastle-on-Tyne District.—Information dated January 7, 1928, shows marked prevalence of smallpox in the Newcastle-on-Tyne area, Great Britain, with many new cases reported daily. The type of the disease is stated to be mild.

HAWAII TERRITORY

Rodent report—Hilo laboratory—November, 1927.—The rodent report from the Hilo laboratory at Hilo, Hawaii, for the month of November, 1927, shows that 13,009 rodents were received and examined during the month. Of these, four were found plague infected. There were no cases of human plague reported, the last case being on August 12, 1927. The last case of rodent plague occurred on November 25, 1927, at Honokaa, Hawaii.

IRAQ

Cholera—November 27–December 3, 1927—Summary.—During the week ended December 3, 1927, 56 cases of cholera with 53 deaths were reported in Iraq. The occurrence was distributed as follows:

Province	Nov. 27-Dec 3, 1927		Summary to Dec 3, 1927	
	Cases	Deaths	Cases	Deaths
Amarah	1	1	184	146
Baghdad	38	38	70	48
Basra			417	337
Diwaniyah			91	50
Diyala	1	1	1	1
Dulaim	1		1	
Hillah	7	4	94	54
Kerbala			43	31
Kut			34	22
Muntafique	8	8	215	139
Ramadi		1	85	64
Total	56	53	1,235	892

JAVA

Plague—Surabaya—November 10, 1927.—Under date of November 11, 1927, Surabaya, Island of Java, was reported plague infected.

MALTA

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported in the island of Malta as follows:

Disease	Cases	Disease	Cases
Broncho-pneumonia	5	Poliomyelitis	1
Diphtheria	5	Scarlet fever	12
Erysipelas	3	Trachoma	48
Malta (undulant) fever	66	Tuberculosis	21
Measles	1	Typhoid fever	74
Pneumonia	4	Whooping cough	3

Population, civil, estimated, 227,440.

MAURITIUS

Plague—Port Louis—September, 1927.—During the month of September, 1927, a case of plague was reported at Port Louis, island of Mauritius.

MEXICO

Mortality, November and December, 1927—Malaria and typhoid fever prevalence—Progreso.—During the month of November, 1927, 64 deaths were reported at Progreso, Mexico, and during December, 1927, 73 deaths. The principal causes of death were stated to be malarial fevers. Severe typhoid fever prevalence was reported, and it was stated that an active campaign of inoculation against the disease was being carried out. Population, 8,877.

UNION OF SOUTH AFRICA

Plague—Orange Free State—Infection among wild rodents—November 13–19, 1927.—During the week ended November 19, 1927, a fatal case of plague was reported in the Orange Free State, Union of South Africa. The case occurred in a native laborer employed on Lang Tlass farm, Heilbron District, situated 8 miles east of Dover Station, who, feeling sick, was proceeding to Johannesburg. He was admitted to hospital and died the following day. It was stated that active plague infection had been verified among veldt rodents on the Lang Tlass farm.

Smallpox.—During the week ended November 19, 1927, outbreaks of smallpox were reported in Bothaville District, Orange Free State.

Typhus fever.—During the four weeks ended November 26, 1927, typhus fever was reported present in the Cape Province, Natal, and Transvaal.

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

ADDITIONAL COPIES
OF THIS PUBLICATION MAY BE PROCURED FROM
THE SUPERINTENDENT OF DOCUMENTS
U. S. GOVERNMENT PRINTING OFFICE
WASHINGTON, D. C.

PUBLIC HEALTH REPORTS

VOL. 43 JANUARY 27, 1928 NO. 4

PREVALENCE OF SMALLPOX IN THE UNITED STATES

The health officers of 37 States reported 28,000 cases of smallpox during 52 weeks ended December 31, 1927. This number is practically the same as the number reported by the same States for 52 weeks in 1925, but it is 2,300 cases more than were reported for the same period in 1926.

The figures are shown in the following table, preliminary weekly telegraphic reports being used for each year:

Preliminary reports from 37 States for 52 weeks

	Cases
1925	28, 070
1926	25, 708
1927	28, 008

The population of these States was about 83,900,000 in 1925, and 87,600,000 in 1927.

During the last four months of the year 1927 the usual seasonal rise in incidence of smallpox occurred, but there were more cases than were reported in either 1925 or 1926. The following table gives a comparison of the preliminary telegraphic reports from 37 States for the last 20 weeks of the years 1925, 1926, and 1927.

Smallpox cases reported by 37 States for 20 weeks

Four weeks ended—	1927	Corresponding week	
		1926	1925
Sept. 10, 1927	493	448	382
Oct. 8, 1927	631	398	380
Nov. 5, 1927	982	761	712
Dec. 3, 1927	1, 920	1, 772	1, 463
Dec. 31, 1927	2, 598	2, 475	1, 646
Total	6, 624	5, 854	4, 583

Both the case rates and the death rates for smallpox vary widely from year to year. The disease now frequently occurs in epidemics which flare up suddenly when the infection is introduced into unvaccinated communities and die out when vaccination deprives the disease of susceptible material.

The following table shows the death rates per 100,000 in the registration area for deaths for the past 25 years, averaged by five-year periods:

Smallpox death rates per 100,000 in the death registration area

1902–1906	2.8
1907–1911	.2
1912–1916	.3
1917–1921	.5
1922–1926	.6

The lowest death rate during these 25 years was 0.1 in 1923, and the highest rate was 6.6 in 1902.

THE OXYGEN DEMAND OF POLLUTED WATERS

RUNNING WATER IS NOT ALWAYS PURE

With a persistence which entitles it to front rank among hygienic fallacies, the idea has long clung to the popular mind that running water, if not always pure, will at least purify itself "in a dozen miles or so." Disastrous consequences following too literal application of this erroneous principle to the selection of municipal water supplies has prompted numerous scientific investigations both here and abroad. A critical review of these researches with a bibliography of over 170 references is given in Part I of a publication entitled "The Oxygen Demand of Polluted Waters," by Chemist Emery J. Theriault, recently issued by the United States Public Health Service as Public Health Bulletin No. 173. Part II of the same bulletin is devoted to the presentation of an extensive series of experiments conducted in the stream pollution laboratories of the Public Health Service.

Briefly, it may be stated that a water contaminated with the organic matters found in sewage and in various industrial wastes does gradually rid itself of such pollution if allowed free access to air. Early studies of this phenomenon of self-purification led to the abandonment of a plausible theory based on the direct action of oxygen on the organic matters, and subsequent research extending over the past 50 years has revealed that the self-purification of streams is essentially a biological process. In this sense the oxygen contained in aerated or running water does not operate as a sterilizing agent, as once believed, but rather as a neutralizing or deodorizing agent for some of the gases resulting from the bacterial decomposition of the organic matters. Dissolved oxygen is also required for the maintenance of fish life. While thus relegated to a secondary rôle, the amount and rate of disappearance of the oxygen which is contained in a given water nevertheless serves as an excellent indicator, first of the threatened disappearance of fish life and, with increasing

pollution, as a warning of impending nuisance conditions. With the understanding that a bacteriological examination is a much better index of wholesomeness or fitness for drinking purposes, it has accordingly become customary to express the pollution of a given water in terms of its demand for dissolved oxygen when reference is made to the threatened disappearance of fish life or to the approach of nuisance conditions.

On the basis of extensive series of observations presented in Part II of Public Health Bulletin No. 173, it has become possible to give numerical expression to the actual rate at which the oxygen demand of a water is satisfied. The outstanding feature of this section of the report is that the rate at which the organic matter is oxidized, while strikingly uniform with a variety of waters, is exceedingly slow. Thus, in a given experiment with Ohio River water collected at Cincinnati, oxygen continued to be used up for fully 300 days and bacteria of intestinal varieties persisted for almost that length of time. Even in the absence of intervening pollution, it would be necessary to allow for a stream flow of several hundred miles before a water, once polluted, could regain its pristine purity. Irrespective of distance from the nearest upstream point of known pollution, it may be safely stated that no river in the United States can now be regarded as hygienically safe without treatment. Conversely, the possibility that a water polluted with sewage might be fully purified by flowing for "a dozen miles or so" becomes too remote for serious consideration.

From a more technical angle, the bulletin under discussion includes data relating to the rate of deoxygenation of polluted river water from which the velocity constants and the temperature coefficient of the underlying biochemical reaction have been computed by the least-squares procedure. The orderliness with which the reaction proceeds compares favorably with that of the purely chemical reactions thus far reported in the literature. This constancy of the rate of deoxygenation of polluted waters is also borne out when the oxygen demand values obtained at various cities are referred to a per capita basis. For the average community, the amount of oxygen required each day for the stabilization of its carbonaceous wastes will be in the neighborhood of 100 grams (0.22 pound) per capita. The findings in this respect are of especial significance, inasmuch as they indicate the possibility of making fair estimates of the ability of a stream to withstand pollution without giving rise to offensive conditions, by a calculation based solely on the contributing population and the volume of stream flow, and without resort to expensive laboratory investigations. Similarly, it would appear possible to estimate the minimum requirements in regard to the treatment of community wastes for the purpose of relieving existing

nuisance conditions. The per capita oxygen demand figure also enters into several other sanitary engineering computations.

Analytical and statistical methods of procedure are given in the four appendices.

This bulletin may be purchased through the Superintendent of Documents, Government Printing Office, Washington, D. C., at 25 cents per copy.

BRITISH COLONIES OF CEYLON, KENYA, AND NIGERIA JOIN INTERNATIONAL OFFICE

The Royal Italian ambassador has officially informed the State Department of the adherence as of January 1, 1928, of the British Colonies of Ceylon, Kenya, and Nigeria to the International agreement signed at Rome December 9, 1907, for the creation in Paris of the Office International d'Hygiène publique.

These colonies have adhered jointly as one unit and have asked to be entered in Class III, with the assessment quota of 15 units as their contribution to the expenses of the office, which will give them the right jointly to appoint a delegate on the Permanent Committee of the International Office.

EXPERIMENTAL BLACK TONGUE OF DOGS AND ITS RELATION TO PELLAGRA

By Joseph Goldberger and G. A. Wheeler, *Surgeons, United States Public Health Service*

CONTENTS

INTRODUCTION [1]

With the beginning of our investigations of pellagra, early in 1914, thought was given to the need for an experimental animal. Accordingly, at our suggestion, Surgeon Edward Francis, United States Public Health Service, beginning December 1, 1914, carried out a

---

[1] By Joseph Goldberger.

feeding experiment in six rhesus monkeys at the United States Marine Hospital, Savannah, Ga. The diet fed those monkeys consisted of hominy grits, 900 grams (2 pounds); rutabaga turnips, dressed, 3.6 kilograms (8 pounds); sodium chloride, 11 grams (0.4 ounce); sirup (a commercial cane and corn compound), 565 grams (1.25 pounds). The feeding was carried on for eight months—that is, to July 31, 1915. Doctor Francis reported that the animals remained healthy, showing no change other than some loss in weight.

The possibility that the dog might serve our purpose first struck us in 1915, on reading in Chittenden's The Nutrition of Man, (1) among other things, the following:

* * * A dog transferred suddenly from a daily ration in which meat and milk are conspicuous elements to a diet in which these are wholly wanting is very liable to show disturbing symptoms almost immediately. One case may be cited in illustration of these statements. On September 29, 1905, dog No. 17, weighing 18.2 kilos was placed on a daily diet composed of 70 grams of fresh meat, 442 grams of milk, 300 grams of bread, and 28 grams of lard. This ration contained 9.06 grams of nitrogen and had a fuel value of 1,465 calories, or 0.5 gram of nitrogen and 80 calories per kilogram of body weight. On October 11 the animal weighed 18.6 kilograms and was in perfect condition. On the 13th the meat was reduced to 34 grams per day, but the milk was increased in amount so as to maintain the same nitrogen intake and fuel value as before. This diet was continued until November 3, a balance experiment covering 10 days from October 22 to 31, inclusive, showing that the animal was laying by a little nitrogen. On November 3 the diet was changed to milk, bread, and lard, the fuel value being maintained at 80 calories per kilo daily, while the nitrogen intake was reduced to 0.30 gram per kilo. On this diet the animal seemed to thrive perfectly, and at the end of two weeks showed a body weight of 18.2 kilograms. November 19 the milk was withdrawn, the bread being increased so as to keep the daily nitrogen intake and the fuel value unchanged. The day's food was now composed of bread and lard solely, but, as just stated, the nitrogen and fuel values were unaltered. In four days' time, however, a change began to creep over the animal; the appetite diminished, and there was apparent a condition of lassitude and general weakness which deterred the animal from moving about as usual.

During the next week the animal grew steadily worse, and would eat only when coaxed with a little milk or with bread softened with milk, the diet of bread and lard being invariably refused. There was marked disturbance of the gastro-intestinal tract; bloody discharges were frequent; the mucous membrane of the mouth was greatly inflamed and very sore; body weight fell off, and the animal was in a very enfeebled condition. This continued until December 4, with every indication that the animal would not long survive, but by feeding carefully with a little milk and occasionally some meat, improvement finally manifested itself, and by December 18 there was good appetite, provided bread was not conspicuous in the food. * * *

In all of the subsequent months, a small amount of meat was a part of the daily food, but as is seen from the table of balance periods, the total nitrogen intake and the fuel value of the food were reduced to even lower levels per kilogram of body weight. Yet the animal gained steadily, until at the latter part of June the weight was considerably above that noted at the commencement of the experiment in the preceding October. Further, the animal was in nitrogen equilibrium or even gaining nitrogen, and in perfect condition of health and

vigor, as is indicated by the accompanying photographs taken at the different periods stated. Especially to be emphasized is the fact that during the last six months of the experiment, the daily intake of nitrogen and the fuel value of the food were as low as or even lower than in November, when the daily diet was limited to bread and lard. The disastrous result which showed itself at once on this latter diet, with all animal food excluded, was not due to low proteid or to deficiency in fuel value, but simply to the fact that the animal for some reason could not adjust itself to a simple dietary of bread and fat, although there was ample available nitrogen and fuel value for the body's needs. Something was lacking, which meat or milk could supply, and this something was indispensable for the maintenance of the normal nutritional rhythm.

This is by no means an exceptional case, but we can cite many other examples of like results where the animal when restricted to a purely vegetable diet, such as bread, pea soup, bean soup, etc., reinforced by an animal fat, quickly passed from a condition of health into a state of utter wretchedness, with serious gastro-intestinal disturbance. * * *

The disturbance of the gastrointestinal tract with inflammation of the mucous membrane of the mouth was to us very suggestive of pellagra, a resemblance that was enhanced by the preventive and curative action attributed by Chittenden to meat and milk feeding, for we had already at that time been impressed with the evidence of a relation between diet and pellagra and with the therapeutic and preventive value of the fresh animal foods in the human disease (2).

Accordingly, at the first opportunity, which came late in the summer of 1916, one of us (J. G.), in association with Dr. Atherton Seidell, tried to repeat Chittenden's experiment in dogs with a bread and lard diet, but without significant result. It was not practicable to do anything more until the summer of 1918. In the meantime Chittenden and Underhill had published a report on "The production in dogs of a pathological condition which closely resembles human pellagra" by means of a diet of boiled peas, cracker meal, and cottonseed oil (3), so that on resuming the study Goldberger and Seidell tried feeding some dogs with the Chittenden-Underhill diet, but again without obtaining significant results. The one experiment that was made was carried on for but three months, at the end of which period it was again found necessary to interrupt this line of investigation.

Work on the problem of an experimental animal for pellagra was not again taken up until early in January, 1922. The dog was again selected for study, but the feeding, it was now decided, should be with a diet of the type that had been found associated with the occurrence of pellagra and believed to be pellagra producing. Accordingly, now in association with Surg. G. C. Lake, United States Public Health Service, the senior writer (J. G.) carried out the following experiment:

On January , 1922, six dogs began to be fed with a diet having the following composition:

Hominy grits	grams	200
Wheat farina	do	57
White rice	do	28
Cowpeas (California black-eye)	do	14
Milk (Pasteurized, market)	cubic centimeters	30
Lard	grams	21
Gelatine	do	40
Sodium chloride	do	10
Calcium carbonate	do	3
Cod-liver oil	cubic centimeters	28
Tomato juice (canned tomatoes)	do	115

The cowpeas were first cooked in tap water for 30 minutes, then the grits, farina (which was used as a substitute for wheat flour), rice, and salt were added and the cooking was continued in a double boiler for about another 40 minutes. At the end of this time the pot of food was withdrawn from the flame and the remaining ingredients were well stirred in. A suitable portion of this diet was served each dog once a day. With the idea of stimulating the appetite, a cake of commercial compressed yeast (about 15 grams) was offered each animal with its daily ration. As, in spite of this, the animals were not eating as well as was thought desirable, the allowance of yeast was later (June 14, 1922) doubled.

One of the six animals having developed an ugly temper, it was chloroformed on August 4, 1922. It had presented nothing of significance up to the time it was killed. On November 9, 1922, the feeding of the remaining five dogs was discontinued. All of them had lost weight and had developed sarcoptic mange, but none presented any other significant pathological change.

This failure, though in a sense disappointing, was not considered conclusive; it was therefore decided to repeat the experiment as soon as the animals were again in good condition.

The experimental feeding in dogs was resumed about the middle of January, 1923, and has been in progress ever since, now in association with the junior author (G. A. W.), who relieved Surgeon Lake about September, 1922, by reason of service exigency requiring the latter's assignment to other duty. In the present communication it is desired to report some of the results obtained.

EXPERIMENTAL FEEDING

EXPERIMENT 1

Our first experiment, essentially a repetition of the one carried out in 1922, was begun on January 16, 1923, with test diet No. 33. (Table 1.) In composition this was essentially the same as the diet used in the 1922 experiment, with the exception that it contained no milk and was not supplemented with yeast. Four days later, that is, on January 20, its composition was modified by reducing the amount

of the cod-liver oil and replacing it with cotton-seed oil, thus making diet No. 34 (Table 2), which was continued without further change to the end. This diet was constructed as a simplified replica of a type of diet found in our field studies in association with and (unless suitably supplemented) believed to be responsible for the occurrence of pellagra (4).

Diets associated with pellagra not infrequently contain some milk and a small amount of some meat; but since we had reason to believe that milk and meat possessed pellagra-preventive properties, and as we desired to work with as potent a pellagra-producing diet as possible, we thought best to exclude milk and meat altogether. As yeast does not ordinarily enter into the diet of the people subject to pellagra, even in their bread, it was thought best on general principles not again to use this even to stimulate the appetite. We had at that time no definite suspicion that it might possess pellagra-preventive action. We included gelatin, first, because we felt that the diet of a normally high-protein-feeding animal should perhaps contain more protein than the diet without some such element would afford, and, second, because at that time we were inclined to believe that the primary etiological dietary fault related to pellagra was an amino acid deficiency, and tests of gelatin in pellagra had already shown that it lacked beneficial therapeutic properties in that disease (4). Wheat farina was used as a substitute for wheat flour in order to avoid as much as possible giving the cooked food mixture a gummy character. The sodium chloride and calcium carbonate were included, with a view to improving the mineral content of the diet, and the cod-liver oil to supply an abundance of the vitamines that might be needed by animals that were to be confined indoors. Incidentally, the cod-liver oil was, in part at least, a substitute for the butter that is at times present in pellagra-producing diets. The canned tomato juice was assumed to be the equivalent of the variable fresh vegetable component of the type of diet ordinarily associated with pellagra.

Five dogs, numbered 1, 2, 5, 6, and 7, were used as test animals. Each animal was kept in a kennel in a room of one of the laboratory buildings. The sides and door of the kennel were of coarse wire screening on a wooden frame. The brick wall of the room formed the back. The floor of the kennel (that of the room) was of concrete. Horizontally across the back of each kennel, about a foot above the floor, there was fastened a board to serve as a bench. The kennel was cleaned daily by freely flushing with water. At irregular intervals the kennels were mopped with soap or disinfectant solution followed by water.

Each animal was provided with fresh drinking water daily, at first in an enameled pan, later in a galvanized iron pot. A weighed amount of the cooked food for one day was served in a similar recepta-

cle. What remained unconsumed at the end of 24 hours was weighed back and thus the daily food consumption was determined. The amount of food offered was, in general, all that the animal would eat.

The effect of this feeding is presented in detail for each animal in the following:

Dog 1.—Male. Acquired December 5, 1921; was one of the test animals in the feeding experiment of 1922.

January 16, 1923: In good condition; weighs 11.1 kilograms; begins test diet No. 33.

January 20: Begins test diet No. 34.

March 8: Food consumption markedly reduced during the past four or five days. There is present to-day a noticeable excess of saliva. The mucosa of the gums of the lower jaw and of the adjacent portions of the floor of the mouth shows irregular patches of congestion.

March 9: Weight, 9.5 kilograms.

March 10: Ate all his food yesterday. The salivation and the reddening of the buccal mucosa have subsided.

March 23: Eyes are slightly watery.

March 30: There is pronounced lachrymation. After a period of about five days from March 9 to March 14 during which the food consumption was consistently excellent, the food taking (appetite) became capricious and has oscillated considerably from day to day. There is present this morning a reddening of the mucosa of the upper lip and of the gums in the region of the oral commissures. The skin of the scrotum appears dry and some flaky desquamation is present. Weight 10.2 kilograms. Temperature at 10 a. m., 38.6°; at 8.45 p. m., 38.7°.

March 31: The skin of the scrotum is desquamating. Temperature at 12 m., 38.1°; at 8.30 p. m., 38.3°.

April 1: Eyes continue slightly watery. Temperature at 10 a. m., 37.7°; at 5 p. m., 38.4°.

April 2: The eyes are watery. There is slight congestion of the mucosa of the anterior portion of the floor of the mouth and of the cheeks. Slight buccal odor. Condition of scrotum unchanged. Weight 9.8 kilograms. Temperature at 12 m., 38.1°; at 5 p. m., 38.1°.

April 3: Over the anterior part of the central half of the skin of the scrotum there is present a slight streaky reddening and scaling. The posterior third of the scrotal skin is pigmented black so that it is not certain whether this is reddened, but there is present a slight but definite scaling over nearly the entire ventral aspect of the scrotum which appears dry. Condition of mouth unchanged. Has eaten very little during the past two days. Temperature at 10 a. m., 38.1°; at 4.45 p. m., 38.1°.

April 4: Scrotal lesion appears unchanged. At about the level of the line of occlusion of the teeth the mucosa of each cheek presents a brownish streak about 3 or 4 millimeters wide. This appears to represent an area of superficial necrosis. The mucosa of the base of the tongue, of the soft palate, and of the fauces appears somewhat similarly affected. Buccal odor is quite fetid. Temperature at 10 a. m., 38°; at 4.45 p. m., 38.3°.

April 5: The condition of the scrotum and that of the mouth are about as they were yesterday. Temperature at 10 a. m., 37.8°; at 4.30 p. m., 38.2°. Was offered about 200 cubic centimeters of fresh milk.

April 6: Condition of scrotum and mouth shows no marked change. Buccal odor continues fetid. Lapped a little of the milk offered. Weight 9.6 kilograms. Temperature at 10 a. m., 38.5°; at 4.30 p. m., 37.9°.

April 7: This morning the reddening of the buccal mucosa appears more pronounced than yesterday. The necrotic areas continue present. There is a moderate increase of saliva without drooling. Buccal odor continues fetid. Lapped but little if any milk since yesterday, but ate a little of the cooked food.

This afternoon there are found patches of redness on the mucosa of the upper lip on each side in the region of the canines. Temperature at 10 a. m., 38.8°; at 4.35 p. m., 38.5°.

April 8: The affected area of buccal mucosa has become more extensive and the inflammation more pronounced. Temperature at 11 a. m., 38.6°.

April 9: There is no notable change. Food consumption has for a week or more been quite irregular and small in amount. Had a hard bowel evacuation during last night. Temperature at 10.30 a. m., 38.2°; at 4.20 p. m., 39.1°.

April 10: The previously noted reddened patches on the mucosa of the upper lip have developed into a sharply delimited band on each side, extending from about the region of the canines back to the cheeks, where they merge in the reddened necrotic lesion of the buccal mucosa. There is slight drolling and pronounced buccal fetor. The skin of the scrotum appears more reddened, and desquamation continues. Had a large, partly formed bowel evacuation during the day. Temperature at 10.30 a. m., 39.1°; at 4.20 p. m., 39.8°. Temperature began to rise yesterday afternoon.

April 11: The inflammation of the mouth now includes the margin of the tongue. There is moderate drooling. Buccal odor is foul. Passed soft blood-stained stool at 4.30 p. m. Temperature at 9.30 a. m., 40°; at 4.20 p. m., 40.7°.

April 12: Has a weakened, dejected appearance this morning. Passed a diarrheal, blood-stained stool during the night with which he is extensively soiled. Buccal mucosa more severely inflamed and necrotic. Marked oral fetor and slight drooling are present. The scrotum shows a pronounced erythematous fringe along the anterior and lateral borders of the desquamating area. The posterior limit of this area is obscured by black pigmentation. There is increased drooling and there have been several diarrheal evacuations during the afternoon. Has eaten nothing since April 9. Temperature at 10 a. m., 40.7°; at 4 p. m., 40.9°.

April 13: Found dead at 7.30 a. m.

Necropsy.—A male fox terrier apparently in good state of nutrition. Weighs 8.3 kilograms. *Rigor mortis* is fairly established. Subcutaneous fat about normal. Skin of the scrotum is dry, red, and scaly. The anterior and lateral limits of the affected scrotal area are well defined; the posterior limit is obscured by dark, normal pigmentation.

The entire buccal mucosa, except that of the anterior portion of the tongue and hard palate, appears, on inspection, to be inflamed and necrotic. The same process involves the mucosa of the pharynx, nasopharynx, larynx, including the glottis and epiglottis, and of about the upper 2 inches of the esophagus. The necrosis seems to be more marked on the mucosa of the cheeks, the base of the tongue, and the soft palate.

The pleurae appear normal. There appears to be some congestion, probably hypostatic, at the base of the lower lobe of the left lung. There is a small hemorrhagic spot with whitish center on the surface of the upper lobe of the right lung. The lower border of the lower lobe of the right lung shows some hypostatic congestion.

The heart and pericardial membranes appear normal.

The liver, spleen, pancreas, kidneys, urinary bladder, and testes appear normal.

The stomach and intestines show an occasional small subserous capillary hemorrhage; otherwise they appear negative on external inspection.

Except for the involvement of the upper 2 inches, to which reference has been made, the mucosa of the esophagus seems normal.

The mucosa of the stomach is markedly congested, with submucous hemorrhages over a rather large area about the pylorus and along the greater curvature.

The small intestine contains a small amount of bile-stained mucus. Scattered throughout the upper half of this gut there are seen small submucous hemorrhages. These coalesce here and there to form small hemorrhagic patches.

The colon contains a small amount of yellowish, slimy mucus. The mucosa is congested and presents numerous submucous hemorrhages. The cecum is similarly affected, but to a lesser degree.

The rectum is empty and is markedly congested with numerous submucous hemorrhages throughout its length. The portion just within the anus presents what appears to be the same process as that seen in the buccal cavity.

Dog 2.—Male. Acquired December 5, 1921; was one of the test animals in the feeding experiment of 1922.

January 16, 1923: In good condition; weighs 8.5 kilograms; begins test diet No. 33.

January 20: Begins test diet No. 34.

February 23: Weight 7.3 kilograms.

March 8: Food consumption since the beginning of this month has been somewhat diminished as compared with that of February. The mucosa of the outer surface of the gums, both upper and lower on both sides, shows areas of redness. The mucosa of the cheeks also is reddened.

March 9: Weight, 8 kilograms.

March 10: The erythema of the mucosa of the gums and cheeks has faded almost completely.

March 22: Has been eating very little during the past five or six days.

March 23: Eyes are slightly watery. The scrotal skin is dry and desquamating in large flakes. Weight, 6.7 kilograms.

March 29: Has eaten little or nothing during the past three days. The mucosa of the upper lip, on both sides, is reddened. The mucosa of the cheeks and of the floor of the mouth is also reddened. All reddened areas have an angry appearance not unlike a severe pellagrous stomatitis. The reddening is not of uniform intensity, there being some patches almost hemorrhagic in appearance, with an irregular grayish surface film resembling a false membrane that is fairly easily wiped off. A fetid buccal odor is present. Buccal secretion is increased. The scrotum shows the remains of a dry, flaky desquamation.

March 30: Has eaten nothing during the past two days. Is lying down and appears disinclined to stand up. Has a listless and dejected look. Buccal odor is very fetid. The outer surface of the jaw is soiled with buccal secretion. The lower lip at the angles of the mouth seems slightly swollen and sags so that the reddened margin is exposed to view. At 5.20 p. m. forced to swallow a bolus containing 10 grams of Seidell's activated solid, immediately after which was seized with a convulsion of a clonic type. Five hours later was forced to swallow a second bolus containing 15 grams of activated solid.

The buccal mucosa is markedly reddened with many eroded spots and with a grayish-amber gelatinous accumulation over large areas of its surface. Has not eaten nor have bowels moved during the past 36 hours. Scrotal condition is unchanged. Temperature at 10 a .m., 40.9°; at 9.25 p. m., 40.7°.

March 31: Appears weaker. Is not eating. Drooling a stringy buccal secretion. Buccal odor continues foul. Buccal mucosa is inflamed, necrotic, and in places ulcerated. Passed a small hard stool coated with blood during the forenoon. About 8.30 p. m. vomited the boluses given yesterday. Passed a soft stool. Temperature at 12 m., 39.2°; at 8.30 p. m., 38.2°.

April 1: Found dead this morning.

Necropsy.—The skin of the scrotum is freshly desquamated with a few partly adherent, thin, dry scales about the periphery. Otherwise, there is nothing of importance on inspection.

The upper surface of the tongue is not appreciably changed from the normal, but the margins at about the interdental space are intensely congested. The under surface of the tongue is congested and of a dark blue color. The floor of the mouth is intensely congested. The pharyngeal, naso-pharyngeal, and laryngeal mucosa and the base of the tongue are intensely congested and present patches of superficial necrosis, as indicated by the presence of patches of a grayish membrane. The hard palate is not appreciably affected. The soft palate is intensely congested. The intensely inflamed mucosa of the lips, gums, and cheeks has a grayish necrotic appearance.

The right lung shows some congestion at the apex and at the base of the middle and lower lobes. The left lung shows hypostatic congestion. The heart seems normal.

The liver, spleen, pancreas, and kidneys appear normal.

The mucosa of the esophagus appears slightly congested. The stomach contains some liquid in which there is a little of what appears to have been part of the bolus of activated solid administered in the evening of March 30. The mucosa presents irregular intensely congested patches near the pylorus and along the lesser curvature.

The small intestine contains a small amount of bile-stained fluid. The upper and middle portions present small irregular patches of congested mucosa.

Under the peritoneal surface of the upper part of the colon there are punctate hemorrhages. Corresponding to the sites of these are seen patches of markedly congested mucosa. The mucosa of the rectum appears normal.

The mucosa of the fundus of the urinary bladder appears congested.

Dog 5.—Bitch. Acquired November 8, 1921; was one of the test animals in the feeding experiment of 1922.

January 16, 1923: In good condition; weighs 8.6 kilograms; begins test diet No. 33.

January 20: Begins test diet No. 34.

January 26: Has been in heat for past three days.

March 23: Weight, 8.3 kilograms.

March 30: Buccal mucosa possibly somewhat reddened. There are four dirty grayish irregular patches on the mucosa of the upper lip; one opposite each canine tooth. Food consumption (appetite) has been much reduced during the past 10 days. Weighs 7.5 kilograms.

No indication of bowel action to-day. Temperature at 10 a. m., 38.6°; at 8.55 p. m., 38.3°.

March 31: No notable change. Temperature at 12 m., 38.5°; at 8.30 p. m., 38.3°.

April 1: No notable change. Temperature at 10 a. m., 38.3°; at 5 p. m., 38.5°.

April 2: Buccal mucosa is inflamed with a necrotic process affecting an antero-posterior elongated area in the region of the molar teeth. Markedly fetid buccal odor is present. Has eaten nothing since March 28. Weight, 7.1 kilograms. Temperature at 12 m., 38.2°; at 5 p. m., 38°.

April 3: The lips and gums show increased redness. The posterior portion of the dorsum of the tongue and the soft palate are decidedly reddened. Had a loose bowel movement during the night. Temperature at 10 a. m., 37.6°; at 4.45 p. m., 38.1°.

April 4: There is some drooling of saliva. Seems weaker. Had a clonic convulsion about noon lasting one-half to one minute. Not eating. Temperature at 10 a. m., 38.1°; at 4.45 p. m., 38.5°.

April 5: Condition not notably changed. Temperature at 10 a. m., 38.6°; at 4.30 p. m., 38.5°. Not eating.

April 6: Appears less dejected. Salivation less marked. Not eating. Weight, 6.8 kilograms. Temperature at 10 a. m., 38.5°; at 4.30 p. m., 38.5°.

April 7: No notable change in condition. Passed small, semiliquid stool during the night. Has eaten nothing since March 28. Temperature at 10 a. m., 38.4°; at 4.35 p. m., 38.6°.

April 13: No notable change in condition during the past week. Not eating. Becoming noticeably emaciated. Weight, 6.1 kilograms. Temperature at 10.20 a. m., 38.3°; at 4.20 p. m., 38.6°.

April 14: Seems weaker. There is a perceptible increase in buccal secretion but without drooling. Condition of buccal mucosa about as previously noted, but the necrotic areas seem to have become somewhat cleaner during the past few days as if tending to heal. Passed a dark, semisolid stool during the night.

The afternoon examination shows evidence of a definite increase in buccal secretion, nearly all of which is apparently swallowed. There is also present a beginning reddening of the labiogingival fold of the upper lip on both sides in the region opposite the canines and the interdental spaces. The mucosa of the cheeks, especially that just back of the angles of the lips, also shows a definite increase in redness. Temperature at 10.30 a. m., 38.2°; at 4.15 p. m., 38.6°.

April 15: The changes in condition observed yesterday afternoon are all more pronounced this morning. In addition, oral fetor has become marked. Very slight drooling. Passed a small, dark-colored semisolid stool this morning. Has eaten nothing since March 28. The test diet is discontinued. Was induced to eat about 20 grams of finely ground fresh lean beef. Temperature at 10 a. m., 38.6°.

April 16: About as noted yesterday except for a possible further increase in the redness of the mucosa of the cheeks and of the upper lip. Passed two diarrheal stools during the night. Was induced to take about 100 grams of fresh beef during the day; ate nothing else. Temperature at 10 a. m., 38.4°; at 4 p. m., 38.6°.

April 18: Has voluntarily taken a little cooked food containing some fresh beef. General condition seems better. The condition of the buccal mucosa seems better, less red.

April 20: There has been a pronounced change for the better in the condition of this animal during the past 36 hours. The inflamed condition of the mouth has improved markedly. Buccal odor much less fetid. Salivation has ceased. Appears livelier than for some time. Eating better of the cooked food containing fresh beef. Has gained slightly in weight during the past week. Weight 6.4 kilograms.

April 27: Condition of the mouth is again about normal. Bowel movements normal. Further history not relevant.

Dog 6.—Bitch. Acquired December 15, 1921. Was one of the test animals in the feeding experiment of 1922.

January 16, 1923: In good condition; weighs 12.6 kilograms; begins test diet No. 33.

January 20: Begins test diet No. 34.

February 14: Threw a litter of 6 pups, 2 of which were dead and macerated; the other 4 died within 24 hours.

March 30: Food consumption (appetite) has been somewhat reduced during the past week. Weighs 10.9 kilograms. The mucosa of the upper lip shows on both sides a sharply delimited band of erythema which in width extends from a little within the free margin of the lip to the labiogingival fold and, in length, from the median line to about the region of the labial commissures. Temperature at 10 a. m., 39.1°; at 9.10 p. m., 38.8°.

March 31: Buccal mucosa about as yesterday. Temperature at 12 m. 39.2°; at 8.30 p. m., 38.8°.

April 1: Reddened bands on upper lip appear about as already noted but there has developed in the past 24 hours a small oval dirty patch on each side in region of apposition to canines. Fetid buccal odor is present. Refused all food yesterday. Temperature at 10 a. m., 39°; at 5 p. m., 39.1°.

April 2: No notable change in condition of the mucosa of the upper lip. The mucosa of the cheeks and the posterior portion of the margin of the tongue have become red. Fetidity of buccal odor is marked. Ate nothing yesterday. Weighs 10.5 kilograms. Temperature at 12 m. 38.9°; at 5 p. m., 39.3°.

April 3: The mucosa of the cheeks presents an irregular patch of superficial necrosis. Ate a small amount of food yesterday. Temperature at 10 a. m., 39.6°; at 4.45 p. m., 38.1°.

April 4: During the past 16 hours the inflammation of the buccal mucosa has taken on a more angry appearance. There have appeared here and there over the affected area brownish necrotic patches of varying form and extent. This process is now present across the mucosa of the soft palate and on that of the upper lip. Buccal secretaion is increased; odor is fetid. Ate a small amount of food yesterday. Temperature at 10 a. m., 40.3°; at 4.45 p. m., 40.0°.

April 5: Ate nothing yesterday. Buccal secretion is profuse; odor is strong. Mouth more markedly affected. The tip and lateral margins of the tongue are reddened. Temperature at 10 a. m., 40.3°; at 4.30 p. m., 40.4°.

April 6: Inflamed condition of the mouth appears to have become more marked; drooling is excessive; odor marked. Ate nothing yesterday. Weighs 9.8 kilograms. Temperature at 10 a. m., 40.3°; at 4.30 p. m., 40.5°.

April 7: Condition of the buccal mucosa has become worse. There is decided increase in the redness of the margin of the tongue, including a narrow strip (about 3 or 4 millimeters wide) of the dorsal aspect of the margin all the way around including the tip; marked drooling of blood-tinged secretion. Buccal odor extremely foul. Has eaten nothing in 72 hours. Temperature at 10 a. m., 40.1°; at 4.35 p. m., 39.4°.

April 8: General condition and mouth symptoms seem worse this morning. Not eating. Temperature at 11 a. m., 36.6°.

April 9: Found dead about midnight last night.

Necropsy.—An apparently well-nourished fox terrier bitch.

The fur of the legs, tail, and sides extensively soiled with saliva. Marked fetid odor about the mouth. Both eyes sunken. Subcutaneous fat abundant.

The mucosa of the lips, gums, floor of the mouth, of all of the tongue except a median strip of the anterior portion of the dorsal surface, of the pharynx, posterior portion of the naso-pharynx; of the larynx, including the glottis and epiglottis and of the soft palate is intensely inflamed and necrotic, with a dirty yellowish slimy layer of necrotic mucosa throughout most of these parts.

The left lung appears normal; the right shows areas of hypostatic congestion in portions of all three lobes. The trachea and larger bronchi seem normal. The pericardium and heart are apparently normal.

The liver, pancreas, and kidneys seem normal. The spleen is perhaps smaller than normal; the central portion is, perhaps, slightly contracted. There are many irregular dark-blue patches scattered throughout.

There is slight injection of the mucosa of the lower portion of the esophagus particularly near the cardiac orifice.

The stomach contains a small amount of bile-stained mucus. The mucosa is slightly injected near the pylorus and along the greater curvature.

The small intestine contains a small quantity of yellowish slimy mucus in places tinged with blood. Along about 3 inches of its length at about the junction of the upper and middle thirds there are scattered some punctate hemorrhages. There are diffuse submucous hemorrhages in the upper portion with here and there circumscribed areas with apparently a beginning necrosis.

The colon contains a small amount of soft, blood-stained feces. The mucosa of the upper portion, including the cecum, is injected, possibly with fine submucous hemorrhages.

The rectum is partly filled with semisolid feces. There is slight congestion of the mucosa near the anal orifice.

The urinary bladder is contracted with the mucosa of the fundus slightly injected.

Genitalia, apparently normal.

Dog 7.—Male. Acquired December 29, 1922.

January 16, 1923: In good condition; weighs 16.8 kilograms; begins test diet No. 33.

January 20: Begins test diet No. 34.

February 9: Eating well. Weighs 18.4 kilograms.

March 9: Nothing notable. Weighs 19.1 kilograms.

March 23: Food consumption has been considerably diminished during the past week. Weighs 19.7 kilograms.

March 29: Food consumption has continued at a reduced though irregular rate. There is some salivation present this morning. The mucosa of the mouth is generally flushed, with marked reddening of that portion of the mucosa of the upper lip that is in opposition to the gum. This reddened area is clearly delimited from the rest of the mucosa of the lip. The mucosa of the soft palate also is notably reddened. A foul buccal odor is present. The nose is moist and there is slight lachrymation.

March 30: The animal appears decidedly weaker than yesterday; disinclined to get up on feet. Eyes are moist; the conjunctivae are reddened. A slight watery nasal discharge is present. There is pronounced drooling of ropy saliva. The lower lip at the angles sags so that the reddened margin is exposed and permits the stringy buccal secretion to flow out. The mouth is more inflamed. The margin and base of the tongue are inflamed but the dorsal surface is not appreciably altered. The anterior portion of the scrotal skin shows a slight reddening and bran-like desquamation. At 5.20 p. m. given 10 grams of Seidell's activated solid in a bolus of graham flour, cornstarch, and cottonseed oil. At 10.10 p. m. given a second bolus containing approximately 15 grams of Seidell's activated solid. Weighs 18.1 kilograms. Temperature at 10 a. m., 39.9°; at 9.35 p. m., 40.7°.

March 31: Has hiccough this morning. Is drooling copiously. Buccal odor is very foul. Has eaten little or nothing during the past three days. Given about 200 cubic centimeters of milk by drench. Temperature at 12 m., 40.2°; at 8.30 p. m., 40.7°.

April 1: Appears considerably weaker. Ate nothing yesterday other than the milk given by drench. Buccal mucosa is more necrotic. The scrotum continues to show desquamation with the anterior and anterolateral margins of the affected area well defined. Had a diarrheal stool last night. Temperature at 10 a. m., 39.5°; at 5 p. m., 39.5°.

April 2: Found dead this morning.

Necropsy.—A large, seemingly well nourished male. Rigor well established. The fur about the mouth is soiled, apparently with buccal secretion; there is a foul odor from the mouth. Sclerae are markedly injected. The anterior part of the scrotum shows an area of erythema and desquamation which is sharply delimited anteriorly.

A considerable subcutaneous fat layer is present.

The mucosa of the upper lip shows evidence of severe inflammation; irregular areas have undergone a necrotic process which gives the appearance of a false membrane. A similar process has affected the mucosa of the lower lip, of the cheeks, of the margin, under surface and posterior portion of the dorsum of the tongue, of the soft palate, of the pharynx, naso-pharynx, larynx, glottis, and epiglottis.

There are fine subpleural ecchymoses below the fourth intercostal space. The left lung is collapsed and shows small areas of hypostatic congestion and consolidation near the margin of the lower lobe.

The upper lobe of the right lung seems normal. The middle lobe of this lung is consolidated and there are small areas of consolidation in the lower lobe. Section of the consolidated areas shows small grayish patches.

The pericardium shows fine capillary hemorrhages. The epicardium shows similar hemorrhages which appear most marked over the interventricular groove and coronary areas.

A rather large quantity of fat is present in the omentum. There are to be observed very fine subserous hemorrhages scattered throughout the length of the intestine.

The liver is about of normal size and is perhaps slightly congested. The kidneys and spleen seem normal. The pancreas presents a suggestion of very fine capillary ecchymosis.

The esophagus appears normal. The vessels of the stomach are injected with what seem to be fine subserous hemorrhages. The mucosa is markedly congested particularly in the pyloric region. The organ contains a small amount of dark green, foul smelling liquid.

Along the middle portion of the small intestine there are scattered small submucous hemorrhages which are more marked in the upper part.

The mucosa of the cecum seems slightly injected; whip worms are present. The large gut is practically empty; its mucosa is injected throughout with numerous fine capillary hemorrhages.

The urinary bladder is contracted. It contains a small amount of urine. There is considerable injection of the mucosa of the fundus.

Testes are apparently normal.

Thus, in from 51 to 73 days after beginning the test, all five animals developed a condition which, certain variations aside, had the same outstanding characters in each. Four of the dogs died; one recovered.

The animals, when sick or at postmortem, or both, were also seen by Drs. Leigh T. Giltner and Jacob E. Shillinger of the Bureau of Animal Industry of the United States Department of Agriculture, and by Dr. M. R. Blackstock, veterinarian, of Spartanburg, S. C. All agreed with us that the condition presented was clinically indistinguishable from that occurring spontaneously in dogs and known to American veterinarians as black tongue.

Athough the study which may be said to have been initiated by the foregoing experiment has been carried on steadily ever since, nearly

four years elapsed before experiment 1, as such, was actually repeated. In its repetition it was found convenient to construct the test diet on a 2,400 instead of the original 1,620 calorie basis, and to use a corn meal of a slightly different character. The test diet was therefore given a different serial number, namely No. 288. (Table 3.) The essential details of the experiment as repeated are set forth in the following:

EXPERIMENT 2 [2]

The methods of caring for, feeding, and observing the test animals were essentially the same as described under experiment 1. Five dogs, numbered 38, 44, 50, 93, and 97, were the test animals. The effect of this feeding is presented in the following for each of the animals:

Dog 38.—Male. Was one of a litter whelped in the laboratory June 26, 1923. Served in various experiments (see experiment 3) and suffered several attacks of experimental black tongue,[3] the latest beginning July 19, 1924. On stock diet No. 156 (Table 4) from March 15, 1927, to April 6, 1927.

April 6, 1927: In good condition; weighs 11.5 kilograms. Begins experimental diet No. 288.

May 3, 1927: Food consumption has been excellent; weighs 12 kilograms.

May 7: Food consumption has continued excellent. Presents a distinctly reddened band or streak about 2 millimeters wide and about 1 centimeter long on the mucosa of the upper lip on each side in the region of the molar teeth. On the right side there is also a reddened irregular circular patch opposite the canine teeth.

May 8: The reddened streaks on the mucosa of the posterior part of the upper lip of each side have extended forward appreciably. The mucosa of the floor of the mouth is slightly injected. Mouth is otherwise about as yesterday. Temperature at 10 a. m., 37.7°.

May 9: The mucosa of the upper lip presents, on the right side, a row of three well-marked and vividly red patches, the middle one of which is opposite the canine teeth; on the left side it likewise presents a row of three reddened patches but these are not so sharply outlined nor so bright as those on the right side. The mucosa of the floor is definitely injected. Temperature at 10.20 a. m., 39.2°.

May 10: The mucosa of the right side of the upper lip continues about as yesterday except that the posterior one of the reddened patches has elongated somewhat and is now continuous with a reddening of the mucosa of the cheek. The reddened patches on the left side of the upper lip are less distinct than yesterday except the posterior one, which has likewise elongated and become continuous, with a flushing of the mucosa of the corresponding cheek. The mucosa of the floor of the mouth continues injected and the anterior faucial pillars have become somewhat reddened. Food consumption continues excellent; weight is 12.2 kilograms. Temperature at 10.32 a. m., 38.9°.

May 11: Mouth appears about as it did yesterday. Temperature at 10.10 a. m., 38.8°.

---

[2] By Joseph Goldberger and L. M. Rogers.

[3] This designation of the experimental disease is here used as a matter of convenience and without prejudice to the question of its identity with the spontaneous disease of this name, presently to be considered.

May 14: The red patches on the mucosa of the upper lip tend to coalesce and to form a band on both sides. The floor of the mouth continues injected. Food consumption was excellent until yesterday when for the first time in fully a month a portion of the daily allowance was left. Temperature at 10 a. m., 38.4°.

May 15: The mucosa of the upper lip on each side now presents a bright red band extending from the cheeks forward to the median line. The cheeks, anterior pillars, and floor of the mouth have become notably more red. There are present small areas of superficial necrotic membrane within the reddened areas on the mucosa of the upper lip; the mucosa of each cheek is fairly well covered with a similar membraneous film. Ate less than half of the food allowance yesterday. Temperature at 9.30 a. m., 39.7°.

May 16: Mouth lesions are about as yesterday but seemingly not so vividly red. The margins of the tongue are reddened and necrotic. There is some salivation and a foul buccal odor is present. Ate nothing yesterday. Temperature at 9.35 a. m., 40.4°; at 2.30 p. m., 40.5°.

May 17: Condition of the mouth is about as yesterday. Not eating. Weighs 10.8 kilograms. Temperature at 8.50 a. m., 41°; at 3.15 p. m. 40.8°.

May 18: Inflamed and necrotic condition of mucosa of lip and mouth is, if anything, more pronounced. Salivation is more pronounced. Seems depressed and weak. When taking the morning temperature the bulb of the thermometer was soiled with thin, brownish feces. At 5 p. m. vomited a moderate amount of thin mucoid fluid. Not eating. Temperature at 9.15 a. m., 41°; at 2.55 p. m 41.6°; at 5 p. m., 41.2°.

May 19: Found dead this morning.

Necropsy.—A seemingly well-nourished animal with a moderate layer of subcutaneous fat and a fair amount of omental and perirenal fat.

The mouth is as observed during life, but the affected mucosa appears here and there of a dark blue tint.

The esophagus presents nothing of note. There is some injection of the gastric mucosa near the pylorus. The small intestine contains some yellowish brown mucous and two or three hookworms. The large intestine presents nothing of special note; the distal portion contains some semisolid feces.

The liver, pancreas, spleen, and kidneys present nothing of note.

The pleural cavities appear normal. The lungs are crepitant, but the right middle lobe and the lower anterior portion of the left upper lobe each presents a dark blue patch of congestion.

The heart and pericardium present nothing of note.

Dog 44.—Male. Was one of litter whelped in the laboratory June 26, 1923. Served in various experiments and suffered several attacks of experimental black tongue, the latest beginning February 4, 1926. On stock diet No. 156 (Table 4) from March 15, 1927, to April 6, 1927.

April 6, 1927: In good condition; weighs 11.8 kilograms. Begins experimental diet No. 288.

May 27: Food consumption has been excellent. On the ventral aspect of the scrotum there is present at about the center an irregular erythematous patch about 2 centimeters in diameter; to the right of this is present another similar but smaller patch.

May 29: The smaller scrotal patch of erythema has faded out while the larger has paled somewhat.

May 30: Scrotal erythema has not notably changed.

May 31: Has continued to eat well. Weight has oscillated between 11.4 and 11.8 kilograms.

June 1: The scrotal erythematous patch seems to have faded at the center and to have extended somewhat peripherally so that there is now present an irregular ringlike band, the band being about 1 centimeter in width.
June 3: The scrotal erythema is again in the form of an irregularly circular patch, the center of the ring having become reddened. The affected skin is dry, with some accumulation of a dried material, possibly of serous exudate.
June 5: Scrotal lesion less red and there is a beginning exfoliation of large flakes.
June 7: Periphery of scrotal lesion is again reddened; desquamation is in progress.
June 10: Scrotal lesion is much less red; desquamation is nearly completed except for a few adhering tabs at the periphery of the lesion.
June 12: Scrotal lesion persists without notable change.
June 13: Scrotal lesion not so red as yesterday.
June 14: Area involved by scrotal lesion has extended and is more red than yesterday.
June 17: Scrotal lesion continues red; there is some desquamation.
June 19: Desquamation of scrotal lesion continues and is in large flakes.
June 23: Scrotal lesion not quite so red as it has been during the past few days, but some redness and desquamation continue in evidence.
June 24: Nearly the entire ventral aspect of the scrotum has become more diffusely reddened. The lesion is sharply delimited. The erythema is more marked at the periphery and there are present some adhering desquamative flakes at points near to or at the periphery.
June 25: The scrotal erythema is less diffuse. Here and there at the periphery of the lesion there are adherent, yellowish flakes, or scales, on an erythematous background.
June 27: The scrotal lesion is less red than it was two or three days ago. Desquamation has increased. Food consumption has been consistently excellent and the weight has been well maintained.
June 30: The scrotal lesion is covered by a brownish yellow epidermal layer that is readily pulled off exposing a glistening new skin beneath. Tabs tend to adhere along the periphery.
July 4: The scrotal lesion presents the appearance of a fairly diffuse reddening affecting almost all of the scrotal surface. The erythema is fairly sharply outlined, but the limits are not clearly perceptible caudally and at the sides on account of the fur.
July 5: The scrotum is reddened, dry, and rough. There is some scaling especially about the margins of the reddened area.
July 8: The scrotum is desquamating in flakes.
July 11: The scrotum is practically normal again.
July 13: The scrotum presents an erythematous mottling.
July 14: Area of scrotal erythema is more extensive.
July 17: The caudal half of the scrotum is erythematous, but the central portion of the affected area presents a yellowish appearance which is found to be due to an epidermal layer that peels off. Presumably this is an exfoliation following an antecedent erythema. Beneath this exfoliating membrane the skin is pale and glistening. Thus the erythema forms a roughly-encircling mottled band about the central exfoliating area.
July 19: The irregular ring-like erythematous band is more red. Anteriorly it presents several eroded patches.
July 20: The entire caudal half of the scrotum is diffusely reddened. There are several large yellowish epidermal flakes attached along the anterior margin of the lesion. The erosions noted yesterday are dry and covered with yellowish crusts. Continues to eat well; weight continues to be well maintained.

July 21: Scrotal erythema less marked; desquamation continues.

July 22: Scrotum seems again of about the normal color but large, dry, yellowish flakes still adhere along the periphery.

July 26: Scrotum continues to desquamate and presents freshly reddened patches at about its center. Food consumption continues excellent. Weighs 12.2 kilograms.

July 27: The scrotal skin is a mottled red. There is only a little desquamation and that at the periphery of the lesion.

July 29: The patchy erythema of the scrotum has become more pronounced.

August 1: The scrotum again is desquamating in large flakes but redness has markedly lessened. Opposite each canine tooth the mucosa of the upper lip presents a suspicious faintly reddened patch.

On July 27, for the first time since the beginning of the experiment, left some (about one-fifth) of the daily ration; on July 29 refused all food; on July 31 again left a small portion of the daily ration.

August 2: On each side of the upper lip there is now a row of small discrete reddened patches. The floor of the mouth is slightly injected. The scrotum is about normal. Weighs 11.8 kilograms. Temperature at 3 p. m., 39°.

August 3: Erythematous patches on the upper lip are brighter. Floor of mouth is more red. Temperature at 10 a. m., 39°; at 3 p. m., 39°.

August 5: Erythematous patches on upper lip have faded somewhat. Temperature at 9.20 a. m., 38.6°; at 3 p. m., 38.6°.

August 6: The mucosa of the upper lip again presents a row of reddened patches on each side. The floor of the mouth is about normal in appearance. Left eye presents a conjunctivitis with considerable lachrymation. Scrotum is about normal.

August 8: Except for a small reddened patch on each side of the upper lip, posteriorly, the mouth is again about normal. The left eye is still watering.

August 10: The ventral aspect of the scrotum again presents an irregular reddened patch. Mouth practically normal in appearance. Left eye is watering.

August 13: The erythema of the scrotum is well marked and has extended peripherally so that it involves all but the most anterior portion of the scrotum. The left eye is still lachrymating.

August 14: The scrotal lesion is about as noted yesterday except that scattered about within the affected area are small yellowish patches. Has eaten well since the first of the month.

August 16: Mild conjunctivitis of left eye persists. The affected scrotal skin appears dry and stiff.

August 18: Scrotal erythema is less marked.

August 19: Scrotal lesion presents a flaky desquamation.

August 20: Both eyes are watering. The scrotal lesion is desquamating. The new underlying skin thus exposed is a mottled red.

August 21: The scrotal lesion has adherent flakes at the periphery. The newly exposed skin is red and presents a number of scattered yellowish, superficially necrotic-looking patches.

August 23: Scrotal lesion is not so red; the scattered necrotic patches seem more extensive. Not eating so well; has refused some food on 5 of the past 10 days. Weight is well maintained.

August 25: Scrotum of normal color except for some crusts at the sites of superficial necrosis; still some adhering tabs along periphery of the lesion.

August 27: Eyes are less watery; scrotum is healing.

August 30: Scrotum is about normal; eyes continue to water; left some food once during past week. Weighs 12 kilograms.

September 1: On the mucosa of the upper lip there is present on each side a sharply outlined reddened band extending from the median line back to the cheeks. The width of the bands is not uniform throughout. The mucosa of the cheeks and the anterior pillars is slightly flushed. The floor of the mouth is reddened.

Has eaten all of the daily ration offered during the past five days. Eyes are still watering. A portion of the left half of the scrotum is slightly mottled red.

September 3: Mouth is not so red. The erythematous mottling of the left side of the scrotum is more pronounced and more extensive.

September 4: Mouth is again about normal in appearance. Eyes continue to water. Scrotal lesion is perhaps less bright.

September 5: The affected scrotal skin has acquired a parchment-like, smooth, yellowish brown appearance.

September 8: Eyes continue to water. Erythema of scrotum is more extensive.

September 9: The mucosa of the upper lip presents on both sides a faint but definite erythematous band. Eyes are watering and there is slight photophobia. Scrotal lesion continues as already noted.

September 10: Erythematous bands on the upper lip are quite bright and sharply outlined. They extend from the median line back to the cheeks which are slightly flushed The mucosa of the floor of the mouth is slightly injected. The affected scrotal skin has a glazed appearance. There is a desquamation beginning over the patches recorded a few days ago as having become pigmented. Along the periphery of the lesion the erythema forms a fairly definite more deeply red encircling zone or band.

September 11: The erythematous bands on upper lip have faded to a considerable degree especially on the right side. The cheeks and floor of the mouth are about normal. Eyes and scrotal lesion not notably changed.

September 13: Mouth is about normal again. The eyes are watering. Very nearly all of the erythematous area of the scrotum has become more or less keratosed and some of its seems pigmented a brownish yellow; desquamation is pronounced. The scrotal lesion has all the well-recognized characters of a pellagrous dermatitis, including a narrow zone of a more pronounced erythema at the periphery of the lesion.

September 16: The erythema of the scrotal lesion has nearly completely faded; the desquamation of a flaky character has made considerable progress, leaving a shiny new skin.

September 19: Eyes continue watery as already repeatedly noted. Desquamation of scrotal lesion has made further advance.

September 20: During the past two weeks has with increasing frequency left some food unconsumed. Weight is 12.1 kilograms and has, thus, been well maintained.

September 22: The mucosa of the upper lip on each side presents a faint but definite, unevenly reddened band. Eyes are watery. The scrotal lesion presents some peripherally adhering tabs.

September 23: The erythematous bands on the upper lip are more definite.

September 24: The erythematous bands on the upper lip are bright and well marked. Mucosa of the cheeks is slightly flushed. The vessels of the mucosa of the floor are engorged. The margins of the tongue, on each side, just back of the tip, are reddened. The scrotal lesion still presents adherent exfoliating epidermal tabs.

September 25: The bands on the upper lip have faded to a very considerable degree. The mucosa of the cheeks is about normal. The floor of the mouth, the scrotum, and the eyes continue about as last noted.

September 27: Erythematous bands have reappeared on the upper lip. On the right side of this lip at about the angle of the mouth there is present a patch of superficial necrosis of the mucosa. On the left side there are several small necrotic patches at about the center of the erythematous band. The floor of the mouth is reddened; the cheeks and anterior pillars are flushed. The left eye is reddened and watery. During the past week some food has been left on all but one of the days. Weight is 11.9 kilograms. Temperature at 10.30 a. m., 39.1°.

September 30: The bands on the mucosa of the upper lip are wider and a deeper red. The mucosa of the cheeks presents patches of necrosis. The margins and the tip of the tongue are more red. There is slight salivation and a foul buccal odor is present. Eyes are watery. Scrotum is negative.

October 1: Food consumption has diminished further. Temperature at 2 p. m., 39.3°.

October 2: The patchy superficial necrosis of affected areas on lip, cheeks, and floor of the mouth is more pronounced. Salivation has increased. Temperature at 9.30 a. m., 39.6°.

October 3: Necrotic process affecting the mucosa of the mouth is still more marked and a pseudo membrane is forming; the lesions are perhaps less red. Has eaten very little during the past 48 hours. Temperature at 10 a. m., 40.8°.

October 4: Food consumption has diminished progressively during the past week. Ate almost nothing yesterday. Weight 10.4 kilograms. Temperature at 9.45 a. m., 40.1°.

October 5: Mouth is necrotic and foul. Lips are stained with a yellowish fluid, probably vomitus. Ate nothing in past 24 hours. Lying quietly in kennel. Temperature at 11 a. m., 36°.

October 6: Died sometime during the night.

Necropsy.—(Partial). A seemingly well-nourished animal with good layer of subcutaneous fat. Inspection of thoracic and abdominal organs shows no gross inflammatory process.

Dog 50.—Male. Acquired September 25, 1923. Served in various experiments and suffered several attacks of experimental black tongue, the latest beginning March 16, 1926. On stock diet No. 156 (Table 4) from March 15, 1927, to April 6, 1927.

April 6, 1927: In good condition, weighs 12.9 kilograms. Begins experimental diet No. 288.

April 19: Some food left well nigh daily during the first week of the test diet. Has eaten all food offered daily during past five days. Weight is 12.8 kilograms.

May 3: Food consumption has been irregular during the past week. Weight is 12.6 kilograms.

May 8: Presents a slight reddening of the mucosa of the floor of the mouth.

May 9: Mouth appears normal.

May 16: Mucosa of the floor of the mouth is probably slightly reddened.

May 17: During the past two weeks some food has been left five times. Weight is 12.5 kilograms.

May 18: The mucosa of the upper lip presents a row of erythematous patches on each side. The floor of the mouth is distinctly reddened.

May 19: Each side of the upper lip presents a well marked reddened band extended from the median line back to the cheeks, the mucosa of which is flushed. The floor of the mouth is distinctly injected. Has been leaving some food daily during the past three days. Temperature at 9 a. m., 37.6°; at 3 p. m., 37.6°.

May 20: Mouth is about as noted yesterday except that the anterior faucial pillars are injected. Temperature at 11 a. m., 39.1°

May 21: The bands on the upper lip are but little changed, if anything they are less bright. There appears to be some superficial necrosis over the central portion of the mucosa of the cheeks. Mucosa of the floor of the mouth less red. Temperature at 9.40 a. m., 38.6°.

May 22: The bands on the mucosa of the upper lip have well nigh completely faded as such, but there are present on each side within the previously affected area a row of three or four reddened patches which are particularly marked on the left side. Mucosa of the cheeks continues flushed. Temperature at 10 a. m., 39.5°.

May 23: Mouth lesions appear much as they did yesterday except that the reddened patches on the upper lip seem more marked. There is present a foul buccal odor. Ate nothing yesterday. Temperature at 10 a. m., 39.2°.

May 24: The reddened patches on the upper lip have increased in dimensions and now present small areas of superficial necrosis. Otherwise mouth lesions are unchanged. Has taken no food in 48 hours. Weight is 11.4 kilograms. Temperature at 10.45 a. m., 39°.

May 25: The reddened patches on the upper lip have coalesced to form a continuous band on each side. There is some superficial necrosis within the area of the lesion on the left side of the upper lip. The mucosa of the cheeks, of the anterior faucial pillars and of the floor of the mouth is bright red. There is some superficial necrosis of the mucosa of the cheeks. Temperature at 9.50 a. m., 38.5°.

Discontinues test diet and begins stock diet No. 156. (Table 4.)

May 28: Affected areas of mucosa of mouth less red; some necrotic patches still in evidence but apparently healing. Has eaten all food offered since the change in diet on May 25.

May 31: Except for a little residual reddening on lips and cheeks, the mouth is about normal in appearance. Continues to eat well. Weighs 12.4 kilograms. Further history not relevant.

Dog 93.—Male. Acquired November 5, 1925. Served in a previous experiment, but has never while under observation presented recognizable evidence of black tongue. On stock diet No. 156 (Table 4) from March 15 to April 6, 1927.

April 6, 1927: In good condition; weighs 14.1 kilograms. Begins test diet No. 288.

April 19: Has left some food three times since beginning this test; weighs 13.9 kilograms.

May 3: During past two weeks has left some food six times; weighs 13.1 kilograms.

May 17: Food consumption during the past two weeks has been much reduced; weighs 11.8 kilograms.

May 31: Food consumption has continued on a much reduced plane; weighs 11.3 kilograms.

June 7: Food consumption during the past week has been much improved; weighs 11.3 kilograms.

June 8: Has eaten all food offered daily during the past four days. This morning there is present a slight but suspicious injection of the musosa of the floor of the mouth.

June 9: Eating well. Floor of mouth is perhaps not so red as yesterday.

June 10: Eating well. Mouth appears normal.

June 14: Has been eating well during the past 10 days; weighs 11.9 kilograms.

June 28: Has continued to eat fairly well, although some food was left twice during the past two weeks; weighs 12.2 kilograms.

July 12: Has continued to gain in weight although there has been some decline in food consumption. Weighs 12.4 kilograms.

July 16: Floor of the mouth is slightly reddened.

July 17: Floor of the mouth is more definitely reddened. There is also some reddening of the anterior faucial pillars. Food consumption is considerably reduced.

July 18: In addition to the reddening of the floor of the mouth and of the fauces there is present an irregular, faintly red patch on each side of the upper lip opposite the canines.

July 19: There is present a faint but definitely reddened band on mucosa of the upper lip on each side. The appearance of the floor and the fauces is about as noted yesterday. There has been a doubt for several days as to the normality of the scrotum. This morning the caudal half is reddened, the erythema being particularly pronounced and sharply limited along the caudal limit of the affected area. Food consumption has become much reduced; weighs 12 kilograms.

July 20: Mouth lesions are about as they were yesterday. Central portion of the ventral aspect of the scrotum is desquamating while posteriorly the reddened area is less bright than it was yesterday. Ate nothing yesterday.

July 21: The bands on the upper lip have become brighter and the mucosa of the cheeks and anterior faucial pillars has become more red. Appearance of the floor of the mouth not notably altered. Scrotal erythema has about disappeared; desquamation continues. Not eating.

July 22: Presents a moderate spastic paraplegia this morning. Is found down in the kennel, but when raised is able to stand and walk with a stiff tiptoe sort of gait. After walking about a minute and after such handling as was needed for an examination of the mouth, etc., a convulsion developed. The convulsion was of a clonic type with marked retraction of the head. Following the convulsion, which may have lasted a minute, the animal seemed dazed and irritable. This condition rapidly subsided and the animal was able to walk back to his kennel. The convulsion was quite like that of polyneuritis. The mouth lesions seem much less red.

As a possible check on the nature of the spasticity and the convulsion, the dog is given 12 grams of an antineuritic preparation in capsules.

July 23: The spastic condition noted yesterday continues little if at all changed. On walking there is the same stiff tiptoe gait. In addition there appears to be some lameness present in the right front leg. No further convulsions have been observed or elicited.

The bands on the upper lip and the redness of the fauces are slightly more pronounced.

Again given 12 grams of the antineuritic preparation in capsules. Has refused all food during the past four days. Temperature at 9.30 a. m., 37.8°.

July 24: Found this morning drooling a bloody secretion. The affected portion of the upper lip and the buccal mucosa are covered with a thick gelatinous pseudomembrane. No evidence of spasticity or lameness. The antineuritic preparation is discontinued and a dose of a commercial dried aqueous extract of yeast (yeast vitamin powder, Harris) is administered. Has taken no food in five days. Temperature at 9.30 a. m., 38.8°.

July 25: At 9.30 a. m. found lying down, but is able to get up and seems to walk normally. Drooling of bloody saliva continues. Upper lip and cheeks are bright red with eroded, ulcerated areas but the pseudomembrane has largely cleared up. Given another dose of the yeast extract. Temperature, 36.5°—3 p. m.: Has had a copious thin brown bowel movement since this morning. Temperature, 36.6°.

July 26: Found dead this morning.

Necropsy.—Fur is soiled. Rigor mortis is marked. There is a considerable layer of subcutaneous fat.

The larynx, except for slight injection of the epiglottis, is normal. The trachea is normal.

Lungs and heart are apparently normal.

The mocosa of the upper lip is bluish-gray in color and is eroded slightly. The tongue is dark but the mucosa is intact. The mucosa of the floor of the mouth is intact.

The esophagus is normal. The stomach contains a yellowish fluid; the mucosa is normal.

The upper half of the small intestine contains some yellowish fluid; the lower half is empty. The mucosa of the small gut appears normal.

The large intestine contains a semiliquid grayish brown material. The mucosa is apparently normal. The rectum is normal.

The urinary bladder is distended; the mucosa is normal.

The spleen, liver, pancreas, and kidneys are apparently normal.

Dog 97.—Male. Acquired January 18, 1926, when about 9 weeks old. Served in a previous experiment but has presented no recognizable evidence of black tongue. On stock diet No. 156 (Table 4) from March 15, 1927, to April 6, 1927.

April 6, 1927: In good condition; weighs 10.4 kilograms. Begins test diet No. 288.

April 19: Food consumption has been uniformly excellent; weighs 10.4 kilograms.

May 3: Has continued to eat well; weighs 10.2 kilograms.

May 5: A small patch of injection is present at about the center of the floor of the mouth.

May 7: The floor of the mouth shows slightly increased injection, particularly about its center.

May 8: The floor of the mouth appears about as it did yesterday. On the mucosa of the left side of the upper lip opposite the canines there is a well-marked, reddened, roughly circular patch about 1 centimeter in diameter; at the corresponding site on the right side there is a similar but faint patch.

May 9: Each side of the upper lip now presents a reddened patch opposite the canines. On the left side there is an additional patch anterior to the canines. The floor of the mouth continues injected. Food consumption has continued excellent.

May 10: On each side of the upper lip there is now present a large reddened patch opposite the canines. Anterior to this there is a similar but smaller patch and posterior thereto there is a reddened streak which merges in a reddening of the mucosa of the cheeks. The anterior faucial pillars as well as the floor of the mouth are injected. Buccal odor is slightly foul. Left some food yesterday, the first time since beginning the test diet. Weighs 10.2 kilograms. Temperature at 10.30 a. m., 39°.

May 11: The reddened patches on the lip have increased in size and are covered with a necrotic film. The mucosa of the cheeks is likewise covered with a necrotic film. The anterior faucial pillars are more markedly reddened. The foul buccal odor is more marked. Temperature at 10 a. m., 39.8°.

May 12: The mucosa of each side of the upper lip now presents a continuous reddened band extending from the cheeks forward. This band presents irregular patches of necrotic membrane. The mucosa of the cheeks, anterior faucial pillars, and the floor of the mouth is vividly red. The mucosa of both cheeks is covered with a gelatinous membrane and the floor of the mouth presents patches of a similar gelatinous film. There is some salivation and

foul odor continues. Passed a thin brownish stool this morning. Refused all food yesterday. Temperature at 10.30 a. m., 40.2°.

May 13: Salivation (drooling) and foul buccal odor more pronounced. Inflamed condition of mouth if anything is more severe. Demeanor is notably subdued. Has taken no food in past two days. Temperature at 10.40 a. m., 40.2°; at 3 p. m., 40.5°.

As the animal seems gravely ill and likely to die within the next 40 or 72 hours and as it is desired to show it at a clinic prepared for the meeting of the American Medical Association, on May 15, treatment is this day begun with an aqueous extract of autoclaved yeast by drench in the hope that life may be sufficiently prolonged.

May 14: The animal, normally very lively, is content to stay quiet in its kennel. The mouth lesions continue necrotic. Drooling continues. Has passed a copious thin brown stool. Given some of the aqueous extract of autoclaved yeast by drench and some by stomach tube. Temperature at 9.45 a. m., 39.9°; at 3 p. m, 40 6°.

May 15: Apathetic in demeanor. Outer surface of jaw soiled with buccal secretion. The mucosa of the mouth seems generally less red and more clean, the ulcerated patches on the upper lip standing out very conspicuously. Given about 200 cubic centimeters of the aqueous extract of autoclaved yeast by tube at 9 a. m. A second portion of 200 cubic centimeters given by tube at 10.30 a. m. was vomited, together with what may have been left in the stomach of the first portion. Temperature at 9.20 a. m., [illegible] 4°; at 3 p m, 39.4°.

May 16: The mucosa of the upper lip and cheeks is less red and cleaner, though showing the scattered superficial ulceration. Margins of the fore part of the tongue are reddened. The tongue as a whole seems shrunken. The mucosa of the floor of the mouth continues red. The anterior faucial pillars are red but less so than a day or two ago. There is some blood-stained saliva on the lips.

Given some aqueous extract of autoclaved yeast in divided does by drench; vomited a portion. Has taken no food in the past five days. Temperature at 9.30 a. m., 40.1°; at 2.20 p. m., 39.6°.

May 17: Found dead this morning

Necropsy.—There is a moderate layer of subcutaneous fat; about a normal amount of omental and of perirenal fat.

The dorsum of the tongue is of a dark-blue color. The margins of this organ, especially anteriorly, are ulcerated The mucosa of the upper lip is ulcerated as observed during life. The floor of the mouth, the cheeks, fauces, and pharynx are involved in the inflammatory process. The lingual aspect of the epiglottis is reddened.

The trachea appears normal. Both pleurae contain fluid with fresh adhesions on the right side. The right upper lobe of the lung presents three or four firm, dark nodules as of hemorrhagic thrombi. Heart and pericardium are normal.

The liver, pancreas, spleen, and kidneys are normal.

The upper part of the esophagus is injected. The pyloric portion of the gastric mucosa is injected.

A tapeworm and some hookworms are present in the middle portion of the small gut. The lower half of the small gut presents submucous injection and a reddish mucus secretion over the mucosa suggesting the oozing of blood into the lumen. The upper part of the large gut appears as does the lower half of the small intestine. The mucosa of the lower part of the large gut shows longitudinal folds seemingly with submucous hemorrhages.

Urinary bladder distended.

Considering the first appearance of the mouth lesions as marking the onset, we find that in from 30 to 117 days after beginning test diet No. 288 all five dogs developed a pathological condition which was indistinguishable from that shown by the dogs in experiment 1. Thus the result of experiment 2 was essentially identical with that of the experiment performed four years previously.

In experiments 1 and 2 the test diet used was, as already stated, designed as a somewhat simplified representation of a type of diet observed in association with the occurrence of pellagra (4). We have also tested, by feeding the dog, the diet, or rather a slightly simplified replica of the diet, used by Goldberger and Wheeler in the feeding experiment in white male convicts carried out in 1915 at the Rankin prison farm of the Mississippi Penitentiary, with which they succeeded in producing pellagra in 5 of 11 volunteer human subjects (5). That test is briefly detailed in experiment 3.

EXPERIMENT 3

The methods employed in the care, feeding, and observation of the test animals were the same as in experiment 1. The composition of the test diet, No. 117, is shown in Table 5. Six dogs, numbered 9, 33, 38, 42, 47, and 48, were used as the test animals. The effect of this feeding is shown in the following for each of the test animals:

Dog 9.—Male. Acquired April 1, 1923. Suffered an attack of experimental black tongue beginning May 15, 1923. On stock diet No. 34C (Table 6) from May 28, 1923, to September 20, 1923. Weight September 18, 1923, 11.9 kilograms.

September 20, 1923: In good condition. Begins experimental diet No. 117.

September 23: Has eaten none of the test diet so far.

September 25: Ate nearly all the food offered day before yesterday; otherwise has eaten none of the test diet Weighs 11.5 kilograms.

September 29: Has eaten an increasing amount of the diet during the past three days.

October 1: Has eaten all the food offered during the past two days. The mucosa of the floor of the mouth is injected and there are patches of redness on the mucosa of both cheeks.

The development of these suspicious signs at the end of a period of 11 days during half of which none of the test diet was eaten suggests the desirability of reconditioning this dog and then repeating the experimental test. With a view, at the same time, of accustoming this animal to the test diet the reconditioning will be attempted by supplementing diet No. 117 with some ground fresh lean beef. Accordingly, 100 grams of lean beef are stirred into the day's allowance of the cooked diet.

October 2: Ate all food offered yesterday; weighs 11 kilograms. The mucosa of the floor of the mouth is quite red. The central portion of the mucosa of each cheek is diffusely reddened. A supplement of 100 grams of fresh lean beef is offered to-day. Temperature at 10 a. m. is 38.8°.

October 5: The mucosa of the mouth is distinctly less red than a day or two ago. Eating supplemented diet well.

October 6: The mucosa of the mouth is well-nigh normal in appearance. Has been eating well. Beginning to-day the allowance of fresh beef is reduced from 100 to 50 grams as a supplement to the daily allowance of 1,000 grams of cooked food into which it is stirred.

October 23: Has been eating well; weighs 12.6 kilograms.

November 6: Daily allowance of food was reduced by about 30 per cent beginning October 25. Has been eating well. Weighs 12.4 kilograms. Daily food allowance restored to previous level, beginning yesterday. Is in good condition.

November 27: Has been eating well. In excellent condition. Discontinues the beef supplement this day but continues diet No. 117, thus beginning a third feeding period. Weighs 12.7 kilograms.

December 4: Food consumption much reduced since discontinuing the beef supplement. Weighs 12.4 kilograms.

December 7: Food consumption during past three days has continued as a reduced rate. Mucosa of the floor of the mouth is suggestively injected.

December 8: No notable change in appearance of the mouth.

December 10: Injection of mucosa of the floor of the mouth is more definite and the mucosa of the cheeks is suspiciously flushed.

December 12: No notable change in the appearance of the mouth. Has taken no food during past two days.

December 14: Appearance of the mouth is unchanged. Ate a little food yesterday.

December 16: Mouth has returned to normal.

December 17: Floor of mouth is again injected.

December 18: Injection of floor of mouth is slightly more definite. Continues to take but small amounts of food. Weighs 11.5 kilograms.

December 19: Injection of the floor of the mouth is still more definite.

December 20: The injection of the floor of the mouth is now quite pronounced.

December 21: The floor of the mouth is intensely reddened; the mucosa of both cheeks and that of the left side of the upper lip are reddened. Food consumption continues small.

December 22: Small reddened patches are now present on the mucosa of the upper lip on each side. The mucosa of the floor and of the cheeks not notably changed in appearance.

December 24: The mouth lesions are more pronounced.

December 26: The mucosa of the floor of the mouth, of the soft palate, of the anterior faucial pillars and cheeks is decidedly reddened. The mucosa of the upper lip presents a bright red patch opposite the left canine and another, less red, on the opposite side. Has been eating considerably better during the past three days. Weighs 11.4 kilograms.

December 29: Mouth lesions are more pronounced. There is now present a well-defined red band along the labio-gingival fold of the upper lip on both sides. Continues to eat moderately well.

December 31: The appearance of the lip lesion is not notably changed; the injection of the other parts of the mouth is less intense.

January 2, 1924: Mouth presents no notable change. Food taking has continued at a moderate rate. Weight continues at 11.4 kilograms.

January 4: All mouth lesions have faded somewhat.

January 5: Mouth lesions seem to have paled further.

January 6: Condition of mouth seems unchanged.

January 7: Mouth lesions seem brighter, especially those on the lip and cheeks.

January 8: Reddening of the mucosa of the cheeks and soft palate has markedly

increased. Food consumption is variable, moderate to poor. Weighs 11 kilograms.

January 9: The mouth lesions are more pronounced this morning.

January 11: The lip lesion is less marked; the other mouth lesions appear unchanged. Begins a reconditioning diet, discontinuing diet No. 117.

January 12: Slight general fading of all mouth lesions. Ate all of the food offered yesterday.

January 13: Mouth lesions have faded further. Eating all food offered.

January 15: Mouth is practically normal in appearance. Further history not relevant.

Dog 33.—Male. Acquired August 6, 1923. Served in a previous experiment and had an attack of experimental black tongue beginning August 28, 1923. On stock diet No. 34C (Table 6) from August 28 to September 20, 1923. Weight on September 18 was 13.9 kilograms.

September 20, 1923: In good condition. Begins test diet No. 117.

September 25: Food consumption has fallen off rapidly and markedly since beginning the test diet. Weighs 13.5 kilograms.

October 1: Has eaten little or nothing during the past five days. Looks dejected. Sclerotics and conjunctivæ are slightly injected. Mucosa of the floor of the mouth is moderately injected. Buccal secretion is increased and quite ropy.

The development of buccal lesions at the end of 11 days, during about one-half of which, as in the case of dog No. 9, little or none of diet No. 117 was eaten suggests the desirability of immediate reconditioning. The reconditioning will be attempted by supplementing diet No. 117 with ground fresh lean beef. Accordingly, this dog is offered 100 grams of fresh beef this day apart from the cooked food.

October 2: Has had a very dark, soft bowel evacuation since last evening. Ate only about 25 grams of the fresh beef offered yesterday. This morning appetite seems to have returned, for he eagerly takes offerings of fresh beef; two offerings of 25 grams each were quickly bolted. Weighs 11.4 kilograms.

Came walking out of kennel on three feet, not using the left hind limb; after walking about a bit began to use this limb but evidently tried to favor it.

There is an eroded, bleeding area at the inner aspect of the right knee; at the outer aspect there are some irregular patches of superficial infection. The skin about the left knee is affected much as is that about the right knee. The skin of the inner aspect of the right thigh has long streaks of redness as if along lymphatics; that of the left thigh is patchily reddened. The skin about both elbows presents irregular erythematous patches and inflamed areas about sites of superficial injection.

The mucosa of the cheeks and of the anterior faucial pillars is moderately reddened. The floor of the mouth is markedly reddened The under surface of the tongue is affected but much less so than is the floor of the mouth.

October 3: Eating the beef but none of diet No. 117. Had two dark, semi-watery stools during the night. Appears fairly lively this morning. There is no lameness in walking, but there seems to be some stiffness in the hind limbs. The mucosa of the cheeks and floor of the mouth about as yesterday. In addition there has developed a small reddened patch on the mucosa of the upper lip in the region of the left canine teeth. The appearance of the skin of the knees, thighs, and elbows is much as it was yesterday.

October 4: Quite alert and lively this morning. Had a very small, dark, semi-liquid stool during the night. Condition of the mucosa of the mouth is about as it was yesterday. The erythematous patches noted yesterday as present at the elbows have nearly completely faded; the other skin lesions are not

appreciably altered. Continues to eat the fresh beef offered, but refuses the other food, diet No. 117. Has passed some dark, liquid stools during the day.

October 5: Is fairly lively. Some fresh beef was rubbed up with a portion of his cooked ration and offered yesterday afternoon. Has not eaten this. Seems to have an aversion to the cooked test diet. The floor of the mouth is less red. Diarrhea continues with dark, semi-solid stools. The condition of the skin about the knees has not undergone appreciable change, but that of the inner aspect of both thighs has improved very much.

October 6: The condition of the floor of the mouth is not appreciably changed, but there has developed in the course of the past 36 to 48 hours two distinct broad, bandlike patches, one on each side of the mucosa of the upper lip in the canine tooth region. Ate the supplement of 100 grams of fresh beef but not any of the cooked food. Temperature at 9.40 a. m., 38.9°.

October 7: The mucosa of the left cheek is quite definitely necrotic this morning; otherwise the mouth lesions are much as yesterday. Diarrhea continues. Ate the supplement of 150 grams of fresh beef yesterday. Temperature at 9 a. m., 39°.

October 8: The mouth leasions are distinctly improved. Diarrhea persists. Ate the 150 grams of fresh beef but none of the other food. Temperature at 9 a. m., 38.8°.

October 9: The mouth lesions are decidedly improved. Bowel evacuations are less fluid. Ate a fair amount of the cooked food during the past 24 hours for the first time in 12 days. The beef was stirred into the cooked food. Weighs 10.4 kilograms.

October 10: Mouth is well-nigh normal. Eating the cooked food with beef in it. Bowel evacuations are semisolid.

October 11: Bowel actions are now formed. The skin lesions are healing but the skin at the right knee appears freshly rubbed. Eating an increased allowance of food with beef stirred in. Beginning to-day there will be stirred into the daily allowance of 1,000 grams of the cooked food (diet No. 117) 50 grams of fresh lean beef.

October 14: Mouth seems about normal. The lesions of the skin about the knees and elbows appear to have been self-inflicted, due to scratching and biting. Continues to rub and scratch the knees and thighs, freshly irritated patches being present.

October 16: Food consumption is somewhat variable from day to day and still considerably below normal. Weighs 10.8 kilograms.

October 18: Found smeared with dark colored, pasty feces this morning. Skin of knees and elbows freshly gnawed and scratched. Seems weak and worn. Took no food yesterday. Had a convulsion during the morning and, judging by his appearance this morning, had a convulsion during the night. Given 50 grams of fresh beef apart from the cooked ration.

October 19: The condition of this dog is about the same as yesterday except that he appears somewhat livelier. Given 100 grams of fresh beef separately. Ate no food other than the meat yesterday.

October 20: Seems more lively this morning. Ate a good portion of the cooked food offered yesterday. Stirred into his food an extra 100 grams of fresh beef thus making 150 grams in all stirred in.

October 21: Patches on knees and elbows are freshly irritated. Eating better. Again an extra allowance of 100 grams of beef is stirred into the cooked ration.

October 22: The floor of the mouth is slightly injected; there is a faintly reddened patch on upper lip opposite the left upper canine. This condition of the mouth may be a residual one following the previously noted mouth lesions. Has eaten well during the past two days.

October 23: Injection of the floor of the mouth is more definite. There is a fairly definite reddening of the mucosa of the upper lip there being present an elongated patch extending forward from the region of the canines on each side. Shows a persistent twitching or jerky movement of the right front and the right hind leg, more pronounced in the latter, which causes him to lose his balance and stagger or fall toward the right. Eating well.

Suspecting that the daily allowance of beef the dog has thus far had is either inadequate or marginal it is this day increased by an extra 200 grams, thus making 250 grams in all, and it is stirred into the cooked ration. Weighs 10.9 kilograms.

October 24: Seems livelier this morning. Incoordination of movements of right fore and right hind leg is less marked. Skin lesions about knees and elbows appear to be healing. Has eaten all food offered during the past four days. A supplement of, in all, 250 grams of lean beef is again stirred into the daily allowance of 1,000 grams of the cooked food (diet No. 117).

October 25: Seems much improved in general condition. Shows some malfunction of right foreleg but this is less noticeable than yesterday. Mouth is about normal. Passed a dark colored, soft stool during the day. Eating all the beef-supplemented food.

October 27: General condition is further improved. Eating well. Fresh beef, 250 grams a day, is being included in the allowance of 1,000 grams of cooked food.

October 30: Has been eating well throughout the past 10 days. Has about returned to normal general condition. Weighs 11.7 kilograms. Passed two soft, dark colored stools to-day.

November 2: Shows new scratch marks and bites of the skin about knees and elbows. Passed a soft, dark stool. Has not been eating quite so well during the past three days.

November 5: Has eaten well during the past two days. Since this animal, though now in a much improved condition, has been slow in recovering it is thought desirable to try a little dry brewers' yeast in place of the 200 grams of extra beef with which the animal's diet has b n supplemented since October 23.

November 6: Continues to eat well; weighs 11.9 kilograms. Food allowance increased 50 per cent.

November 13: Has made marked improvement. The skin condition has healed. Has made a marked gain in weight. Weighs 13.5 kilograms.

November 27: Has been eating well and has been gaining in weight. Weighs 15 kilograms. Seems in good condition. Further history not relevant.

Dog 38.—Male. One of a litter whelped in the laboratory June 26, 1923. Served in previous tests and previously had black tongue, the latest beginning about December 24, 1923. On reconditioning diets from December 27, 1923, to January 29, 1924.

January 29, 1924: In good condition; weighs 8.2 kilograms. Begins test diet No. 117.

February 5: Food consumption has been excellent throughout the week since beginning this test. Weighs 8.7 kilograms.

February 12: During the past five days food consumption though good has been at a considerably reduced rate. Weighs 8.8 kilograms.

February 14: Presents this morning, 16 days after beginning the test diet, a blotchy reddening of the floor of the mouth.

February 17: The floor of the mouth is definitely injected. A small reddened patch has appeared on the mucosa of the upper lip opposite the left canine tooth. Food consumption at a reduced rate continued. This animal presents

definite signs of the beginning of our experimental pathological condition; test diet No. 117 is discontinued and reconditioning is this day begun.

February 18: Injection of the floor of the mouth has faded slightly.

February 22: Mouth lesions have about cleared up. Further history not relevant.

Dog 42.—Male. One of a litter whelped in the laboratory June 26, 1923. Served in previous tests and has had experimental black tongue, the latest attack beginning February 14, 1924. On a reconditioning diet from February 20 to March 1, 1924.

March 11, 1924: In good condition. Weighs 10.9 kilograms. Begins test diet No. 117.

March 18: Food consumption during the past week has been excellent. Weighs 11.3 kilograms.

March 25: Food consumption continues very good but during the past five days at a somewhat reduced rate. Weighs 11.6 kilograms.

April 1: Food consumption has continued at a reduced rate. Weighs 11.5 kilograms.

April 2: The mucosa of the upper lip on each side opposite the canines is slightly mottled red. The left border of the floor of the mouth shows patches of slight injection.

April 3: The reddening noted yesterday has well nigh completely faded.

April 4: Mouth seems normal this morning.

April 7: The floor of the mouth is intensely reddened as are also the mucosa of the cheeks and labio-gingival folds of upper lip on both sides.

April 8: If anything, the mouth lesions noted yesterday are more marked this morning. Food consumption has continued at a moderate rate. Temperature at 10 a. m., 39°. Weighs 11.5 kilograms.

April 10: Mouth lesions show no signs of improvement. Continues to eat moderately well.

April 11: A few irregular patches of superficial necrosis have appeared on floor of mouth and on the mucosa of the left cheek. Temperature 2 p. m., 38.7°. Test diet is discontinued, reconditioning is begun.

April 13: Mouth lesions are fading.

April 15: Mouth very greatly improved. Weighs 12 kilograms.

April 20: Mouth is again normal in appearance. Further history not relevant.

Dog 47.—Male. Acquired August 18, 1923 Served in a number of previous tests. Has already had experimental black tongue, the latest attack beginning January 7, 1924. On reconditioning diets from January 11 to March 11, 1924.

March 11, 1924: In good condition. Weighs 11.9 kilograms. Begins test diet No. 117.

June 23: This animal after a period of about 10 days of excellent food consumption, developed a capricious and slowly diminishing appetite. Has presented in other respects no evidence of any pathological condition during the 104 days since the beginning of the test.

The experiment is this day discontinued by reason of difficulty in the procurement of sweet potatoes of proper quality for the diet.

Dog 48.—Bitch. Acquired August 20, 1923. Served in some previous tests resulting in experimental black tongue. The latest attack began about November 5, 1923. Had an attack of an infective ulcerative stomatitis beginning December 17, 1923. On a reconditioning diet from December 20, 1923, to January 29, 1924.

January 29, 1924: In good condition. Weighs 6.7 kilograms. Begins test diet No. 117.

February 16, 1924: Presents an ulcerated or eroded-looking patch of the mucosa of the right cheek near the faucial pillar.

February 19: Has been eating fairly well though at a slightly reduced rate. Weighs 6.5 kilograms.

February 20: The ulceration of the mucosa of the right cheek has about healed.

February 22: Mouth is about normal.

March 25: Food consumption has been at a somewhat diminished rate. Weighs 6 kilograms.

March 27: A small pigmented and slightly reddened ulcerated patch has appeared on the mucosa of the upper lip opposite the right interdental space. There are also a few small slightly pigmented ulcerated patches along the central portion of the mucosa of the right cheek.

March 29: The lip lesion has become somewhat more pronounced and the patches on the mucosa of the cheek have coalesced into a dark brownish pigmented band, about 0.5 inch wide extending from the right faucial pillar forward. This seems to be the infective ulcerative stomatitis again.

March 31: Mouth shows no further notable change.

April 1: Food taking is rather variable. Weighs 6 kilograms.

April 2: A small pigmented ulcerated patch has appeared on the back part of the mucosa of the left cheek. The pigmented lesion on the right cheek and that on the upper lip not notably changed.

April 8: Mouth lesions appear cleaner with a noticeable tendency for the ulcerations to heal. Food taking variable and diminished. Weighs 5.6 kilograms.

April 10: The pigmented, ulcerated patches on the lip and cheeks have about healed.

April 22: There appears to be a renewal of ulceration over the previously pigmented patches on the mucosa of the cheeks. Food consumption has been somewhat further reduced. Weighs 5.3 kilograms.

April 23: The pigmented, ulcerated patches are more marked. There is a fetid buccal odor present. Has taken no food during past two days.

April 24: The floor of the mouth seems somewhat injected. No other notable change in mouth condition.

April 29: Eating poorly; becoming anaemic and emaciated. Weighs 5.2 kilograms.

April 30: Ulcers on cheeks have healed but there remains slight pigmentation of the posterior part of the mucosa of each cheek. Floor of mouth is negative.

May 20: Has been eating moderately well, maintaining her weight, which continues at 5.2 kilograms. The mucosa of the floor of the mouth is suspiciously blotchy red, 111 days since beginning the test.

May 21: The floor of the mouth, particularly about the root of the tongue is definitely reddened, confirming yesterday's suspicion. There are present also circumscribed erythematous patches on the mucosa of the upper lip of each side in the region of the canines.

May 22: Mouth is about as yesterday but with a new reddened circumscribed patch on the mucosa of the upper lip on left side near the angle of the mouth.

May 23: The reddened patches on the lip and the floor of the mouth have faded somewhat.

May 26: Only a residual indication of the reddened condition of the floor of the mouth is appreciable.

May 27: Mouth is about normal. Weight continues at 5.2 kilograms.

May 31: The floor of the mouth, particularly the left half, shows a streaky reddening.

June 2: Mouth again about normal.

June 10: Weight continues at 5.2 kilograms.
June 17: Weighs 5 kilograms.
June 18: The floor of the mouth and the mucosa of the cheeks and of the upper lip on both sides are suspiciously reddened.
June 19: Mouth condition is more pronounced.
June 20: The floor of the mouth, the mucosa of the cheeks, and of the upper lip are markedly injected. The reddened spots on the upper lip appear to be coalescing to form the bandlike lesion. The animal is quite emaciated and somewhat sluggish. Temperature at 9.45 a. m., 38.4°.
June 22: The reddened areas show a slight superficial necrosis especially noticeable on the floor of the mouth and posterior part of the cheeks.
June 23: The superficial necrosis of floor of the mouth and of the mucosa of the cheeks has extended with a separation of the necrotic film or membrane over parts of the affected area. There are a few necrotic patches over the reddened bandlike lesion of the upper lip. Temperature at 9.50 a. m., 38.7°.

Experiment is this day discontinued by reason of difficulties in procurement of sweet potatoes of the desired quality for the test diet. Reconditioning begins.
June 24: Eating has been very poor recently; ate almost nothing during the past four days. Weighs 4.9 kilograms.
July 3: Mouth lesions practically healed. Further history not relevant.

Within a period not to exceed 111 days, five of the six animals developed definitely recognizable evidence of a pathological condition indistinguishable from that shown by the test animals in experiments 1 and 2. The one animal (No. 47) which showed no recognizable evidence of the condition was fed the test diet during 104 days at the end of which period it was found necessary, by reason of difficulties in securing sweet potatoes of satisfactory quality, to discontinue the experiment. The possibility is therefore not excluded that this animal would also have developed the condition had the feeding been carried on for a longer period.

It may be here stated that, during the period of almost five years that the feeding study, of which the foregoing experiments form a part, has been in progress, we have induced with various modifications of the foregoing diets (8) the pathological condition detailed in the protocols above presented one or more times in each of a considerable number of dogs and have found that in all essentials, as we have learned to recognize them, the picture has always been the same. Therefore, for the sake of brevity in the presentation of the further results of that study, it will be helpful at this point to present a summary of our observations of this experimental condition.

THE EXPERIMENTAL DISEASE

After a variable period during which the animal's food consumption (appetite) may have been consistently good or may have varied irregularly, examination of the mouth reveals a more or less extensive patch, or patches, of reddening of the mucosa of the upper lip, or of the mucosa of the cheeks, or of that of the floor of the mouth, or of

all three with or without a flushing of the anterior faucial pillars and, at times, of the soft palate.

The initial reddening of the mouth is at times very fleeting. It may fade completely after a few hours or a few days, only to appear again after a variable interval. It may do this repeatedly, the attack taking on a seemingly intermittent or relapsing, and, in exceptional instances when thus sufficiently prolonged, a somewhat chronic, character.

The initial reddening of the mucosa of the upper lip varies considerably with respect to extent, site, and intensity. It may appear at first as a single patch on one or both sides, most commonly in the region of apposition to the canine teeth; or it may appear in the form of a horizontal row of two or more discrete, irregularly circular patches of various diameters, or finally it may appear as an elon ated red streak or band. As the attack progresses, the lip lesion, if it did not appear as such at first, develops on both sides into a sharply delimited, vividly red band. When fully developed, this band of variable and irregular width may extend on each side from the median line in front back to the cheek in the reddened mucosa of which it merges. The flushing of the mucosa of the cheeks and of the floor of the mouth may be streaky at first, but later becomes diffuse. The red of the lip lesion and of the floor of the mouth takes on a peculiar vermilion tint that is very striking and almost, if not quite, distinctive.

The tongue is ordinarily but slightly, if at all, affected until the attack is well advanced. There then develops a reddening of a segment of variable length of the lateral margin just back of the tip or at the indentations made by the canine teeth.

Sooner or later, frequently within 24 hours after the appearance of the lip lesion or of the reddening of the mucosa of the cheeks or of the floor of the mouth, irregular patches of superficial necrosis develop here and there within the reddened areas. These necrotic patches may appear of a brownish or grayish tint. At times there forms over the affected mucosa a grayish, jellylike film or pseudomembrane, which is readily removed by wiping with a bit of absorbent cotton. The necrotic process may also affect the mucosa of the base of the tongue, the soft palate, the fauces, and the gums. It frequently affects the lingual aspect of the epiglottis, but this is ordinarily not perceptible during life. At times the margin of the tongue, especially where indented by the canine teeth, becomes affected by a severe necrotic process and may take on a dark-blue tint. Exceptionally the entire free portion of the tongue takes on this color.

As the stomatitis progresses, a fetid odor and an increase in buccal secretion develop. With the advance of the stomatitis the odor

becomes more and more foul, frequently becoming extremely disgusting. The salivation may show itself at first only as a slight excess of moisture on the lips; later there is drooling, frequently of a stringy, egg-white sort of secretion, occasionally blood stained, which may hang from the corners of the mouth.

The appearance of the stomatitis is usually preceded by a falling off in (appetite) food taking. In exceptional instances, food taking may be excellent until after the development of the stomatitis has made considerable progress. In either event, as the attack proceeds, food consumption more or less rapidly declines and soon entirely ceases. If the attack is a rapidly progressive one, or as the advanced stage is reached, the animal does not again voluntarily take food, largely doubtless because of the inflamed condition of the mouth. At this stage the animal may perhaps thrust its muzzle into water as if it desired some but may make no effort to lap any of it.

In the terminal stages of the attack, vomiting or regurgitation, especially if forced feeding is attempted, may take place Hiccough has been observed. As the attack progresses the bowel evacuations generally become small and dry—constipated. Constipation may persist to the end Toward the end i some cases, however, this may be succeeded by diarrhea with small, brown, liquid and, at times, bloody evacuations

The temperature at first continues at or only slightly, if at all, above its normal level (38° to 39° C.); later the temperature rises and within 24 to 48 hours reaches a point somewhere between 40° and 41° Having risen, as a rule it remains up until the end approaches, when almost invariably it declines rapidly and almost always continuously to the end. In exceptional instances, a day or two after its first rise the temperature may drop (intermit) for some 24 hours, only to rise again to the same or higher level than that first attained. We have come to regard the rise in temperature as a sign of the gravest prognostic import. The chance of saving the life of the animal by therapeutic interference rapidly diminishes the longer treatment is delayed after the rise in temperature has taken place.

Aside from a variety of accidental skin conditions and in one case (dog 33, experiment 3) a self-inflicted dermatitis from biting and scratching, presumably because of itching or burning sensations, we have observed in some of the cases in males an eruption on the scrotum which appears to be a part of the picture we are considering. This eruption is a sharply marginated, desquamating, or exfoliating lesion involving a variable area of the ventral aspect of the scrotum. It may or may not be preceded by a recognizable erythema. Whether preceded by an erythema or not the desquamating area is frequently seen to present a narrow erythematous limiting zone or margin. In cases in which the beginning erythema occurs, the area of skin so

affected may be found, after a day or two, to have become glazed and at times pigmented a light brownish tint. This glazed, brownish epidermal layer seems to become thickened and sooner or later begins to desquamate or to exfoliate, leaving a smooth glistening new skin. At the periphery of the lesion there is left at first a ragged fringe which gradually clears up. Its evolution, margination, peripheral erythematous zone, and course distinguish it from other scrotal lesions that we have so far observed in the dog. It occurs in some 40 or 50 per cent of attacks in the male; we have not observed the eruption on the external genitalia of the female. In its mode of development and distinguishing characters (restricted localization aside) this dermatitis is frequently strikingly like, indeed can not be distinguished from, that which occurs in pellagra in man. This eruption may precede, coincide with, or follow, the development of the stomatitis.

The demeanor of the animal in the early stages presents little or nothing to suggest that it is sick. Toward the close, however, its liveliness diminishes notably and it becomes more and more apathetic. As the animal's food intake diminishes and ceases, its weight declines. If, as is usually the case, the course of the attack is acute or rapid and the animal dies within a week or 10 days there is, on inspection, no notable emaciation; if, as is much less common, the progress of the attack is of a prolonged, intermittent, or relapsing character, emaciation may become extreme.

Lachrymation with or without notable conjunctival injection has been observed in a few cases; a slight watery nasal discharge has occurred in still fewer instances. These may have been accidental manifestations—not properly a part of the experimental condition.

Convulsions of a clonic type have occurred in a few cases; see for example dog 5 in experiment 1 and dog 93 in experiment 2. Whether these are part of the disease proper or are due to a deficiency in antineuritic—as may in some if not all instances of convulsions in our experience have been the case—is not clear. In one of our cases a marked flaccid paraplegia and in another a slight weakness in the hind limbs was observed that could hardly have been due to antineuritic deprivation.

At necropsy one finds very little of significance in addition to the lesions of the mouth observable during life. These may present a somewhat different coloring post mortem, particularly if any considerable interval has elapsed between time of death and the examination. The reddening of the mouth lesions may be much less marked and these may be covered with a greenish gray instead of a grayish or brownish film or deposit. Frequently, too, one finds the margin or the whole free portion of the tongue of a dark-blue or black color when but little, if any, of this was present during life. There may

be some injection and at times some superficial necrosis of the mucosa of the lingual aspect of the epiglottis. Quite exceptionally the laryngeal mucosa may be injected. The mucosa of the upper part of the esophagus seems at times to be involved in the inflammatory process and thus may in some cases be found considerably injected. The stomach and intestines ordinarily present nothing notable. In some instances there may be in the course of the intestinal tract areas of congestion of the mucosa with here and there submucous hemorrhages and oozing of blood into the lumen of the gut. Occasionally the rectal mucosa is found deeply injected with some patches of superficial necrosis. Punctate subserous hemorrhages at times occur along the large and the lower part of the small intestine. Occasionally the vaginal mucosa may be injected. The other organs as a rule present to the eye nothing of note.

The scrotum, if affected during life, shows the scaling and margination of the dermal lesion; but the reddening, if any were present during life, may be but little appreciable.

Clinically, the distinctive early marks of the condition are the stomatitis, particularly the bilaterally symmetrical, sharply marginated erythematous bandlike lesion of the upper lip and the vivid red injection of the floor of the mouth. In some animals, when excited and panting, the buccal mucosa is likely to be generally flushed. This should, however, cause no difficulty or confusion nor should a peculiar infective ulcerative stomatitis occasionally encountered in dogs do so. This ulcerative stomatitis (see dog No. 48, experiment No. 3) is characterized by the occurrence on almost any part of the mucosa of the mouth of one or more variable-sized ulcers which are accompanied by a brownish pigmentation. These ulcers may have about the base a small reddened zone. This lesion which is primarily an ulcer with brown pigmentation of the mucosa differs markedly from the erythema with secondary superficial ulceration of the experimental condition. The peculiar dermatitis of the scrotum may appear considerably earlier than any recognizable lesion of the mouth, but if not fully marked may be difficult to distinguish from some of the other occasionally encountered accidental dermal lesions of the scrotum. We have, therefore, never used the scrotal eruption alone as a diagnostic criterion.

In our work we have commonly used our animals repeatedly so that many have had a number of more or less marked successive attacks. So far as we are able to judge, one attack confers no appreciable increase in resistance to another, nor does it appreciably diminish the resistance to a subsequent attack provided the animal is adequately reconditioned by proper feeding for a sufficiently long period during the interval. Susceptibility to attack appears not to

be influenced, at least not to any outstanding degree, by either age or sex.

The response to proper treatment when this is not too long deferred is commonly prompt and striking. The temperature, if it has already risen, declines to normal; the redness of the mouth rapidly subsides; the necrotic areas clean up, leaving healthy, superficial ulcerations which rapidly heal; the animal begins to eat, and within a week or 10 days little may be left of the grave pathological process that may have been present when treatment was begun.

Relation to black tongue of dogs.[4]—It has already been stated above that both our consultants and ourselves found the condition experimentally induced by us indistinguishable from the disease occurring spontaneously, known to American veterinarians as black tongue.[4]

Those unfamiliar with the spontaneous disease may find the following clinical description and the postmortem findings in two dogs, taken from a paper by Wheeler, Goldberger, and Blackstock (6), of interest for comparison with the above experimental condition:

> Onset is rather abrupt, with lassitude, loss of appetite, occasionally vomiting and thirst; the animal, though trying often, may be unable to take water. The mouth early gives off a characteristic offensive, nauseating odor and soon becomes sore. Salivation develops early, and the drooling saliva may become bloody.
>
> The buccal and lingual mucosa becomes more or less extensively injected and inflamed. In some cases the congestion becomes very marked, the mucosa then presenting more or less extensive purplish red areas. The tongue, more particularly the free anterior portion, may be thus affected; the margin may be bright red. Both tongue and cheeks may become covered with a dirty, gray, shiny coating suggestive of a diphtheritic membrane * * *.
>
> The mouth may present erosions and ulcers. Vomiting may occur and either constipation or diarrhea may be present; constipation is more often a symptom of the onset, diarrhea of the later stages. When there is diarrhea the stools may be bloody, particularly in cases with fatal termination. The temperature may at times be considerably elevated.
>
> The disease appears to end in death in about 75 per cent of the cases, running its course in these in some four to eight days.
>
> The American literature on the postmortem findings is extremely meager. The following notes are of two necropsies made * * * August 11, 1921. One (dog) had died 24 hours and the other 10 to 15 hours previously.
>
> In both animals the lingual and buccal mucosa was found markedly but unevenly congested, the congestion involving the mucosa of the lips and opposing gums. There was also some congestion of the mucosa of the larynx and epiglottis.
>
> The gastric mucosa showed a patch of moderate congestion in the region of the pylorus.
>
> In one of the dogs there was marked congestion of the mucosa of the large gut throughout its whole length, including the rectum; in the other no gross change in this part of the bowel was apparent.
>
> The contents of the gastro-intestinal tract was small in amount; in one it was seemingly of a mucus nature, in the other more watery. In both it was yellow-

[4] Synonyms: Stuttgart dog epizootic; typhus der Hunde (dog typhoid); typhus of dogs; gastroenteritis hemorrhagica; southern canine plague; sore mouth of dogs

tinged, probably from the medication administered just before death. This yellow tinting was also observed to affect the lingual mucosa and the buccal secretion.

Examination of the lungs, heart, liver, spleen, and kidneys disclosed no gross lesions.

Of interest in this connection, too, is the following from a case report by Goldberger, Tanner, and Saye (7):

On examining the sick animal (fifth day of sickness) we found that the conjunctivæ, especially the conjunctiva of the right eye, were much reddened, and there was some purulent secretion within the lower lid of the right eye. The owner stated that the eyes had been sore for about three weeks.

There was some drooling of ropy saliva. The lower jaw was soiled with this, and the forelegs where the jaw had rested on them were smeared with saliva and particles of garden earth.

The mucosa of the lips was found deeply inflamed with necrotic patches, especially on that of the upper lip at the site of contact with the canine teeth.

The jaws were closed and there was some resistance to our attempt to open them.

The buccal mucosa was found violently inflamed, and the tip and adjacent margins of the tongue were red. A very disagreeable odor was present.

Seen the next day the animal was

* * * unconscious and evidently dying. The condition of the mucosa of the lips and cheeks was as already noted. In addition it could be seen that the tongue presented a dark bluish patch on the left margin, one on the right margin, and a third on the under surface.

The floor of the mouth, which could not be inspected satisfactorily at our first visit, was now found to be severely inflamed. There was evidence that the animal had had a blood-streaked semiliquid bowel evacuation.

About three hours after death

* * * rigor mortis is quite well marked.

Conjunctiva of right eye is pale. The left eye shows more marked inflammation than during life. Yesterday the right eye was the more severely inflamed. Some purulent exudate in the conjunctivæ.

The mucosa of the upper lip and of the labio-gingival fold is severely inflamed, with irregular, superficial, necrotic-appearing patches. This inflammation extends down on the gums, and the affected area is limited by a rather sharp line of hyperemia slightly, but at a varying distance, above the gum margin, being farther removed at the canines than at the molars.

The mucosa of the lower lip is involved in a similar process. No hyperemic limiting line is appreciable, however, although the inflammation does not seem to extend quite to the gum edge.

The buccal mucosa presents an inflamed and superficial necrotic process quite like that of the lips. The mucosa of the soft palate presents a quite similar inflammatory and superficial necrotic process as that of the lips and cheeks.

The mucosa of the dorsum of the tongue is grayish white in appearance, except over about the anterior third, where it is reddened, the redness being uneven, patchy. The redness is particularly marked along the margins of the tip and anterior third of the tongue. On the right side the redness extends back for about two-thirds of the length of the tongue, involving more particularly the under aspect of this margin. On the inflamed reddened portion of the left margin of the tongue there are some indentations or erosions with a grayish surface. This

part of the margin presents two slightly separated segments, each about 3 or 4 millimeters in length, which are especially deeply inflamed and darkened in color. The right margin of the anterior portion of the tongue presents, like the left, a deeply inflamed hyperemic appearance, with a necrotic patch a little back of the tip.

The mucosa of the under surface of the tongue presents some superficial erosions or ulcers, three on the right side and two on the left. The eroded or ulcerated patches on the under surface of the tongue measure about ½ by 1 or 2½ centimeters. The mucosa of the floor of the mouth presents much the same inflamed appearance as does the buccal mucosa, except that the superficial necrotic process does not seem quite so severe. On each side of the frenum of the tongue there is a conspicuous oval fold of mucosa which is involved in the inflammatory necrotic process; each fold measures about ½ by 1½ centimeters.

The mucosa of the tonsils shows a marbled hyperemic appearance.

The mucosa of the pharyngeal aspect of the epiglottis is deeply congested. The mucosa of the fold extending from the base of the tongue to the epiglottis on the right side presents two superficial ulcerations. The mucosa of the epiglottis, tracheal as well as pharyngeal aspect, is deeply congested.

The trachea appears normal.

The middle lobe of right lung shows some irregular patches of consolidation and, possibly, edema. The left lung appears approximately normal.

Corresponding to the interventricular septum anteriorly there are a few punctate subpericardial hemorrhagic spots. The heart muscle and endocardium appear normal.

The liver appears normal. Adhesions (old) are present between the spleen and the omentum at the inner end of the spleen, at and near which there are present some extravasations along the line of some of the blood vessels of the omentum.

On the under surface of the omentum there are scattered dark points which, on close examination, appear to be minute varicosities of the minute omental vessels.

There is some adhesion of the capsule of the kidneys, a little of the cortex tearing away when the capsule is stripped.

The vaginal mucosa shows an inflammatory process with a superficial necrosis.

The esophagus presents irregular elongate patches of congestion, possibly representing effused blood. In the region of the pylorus of the stomach there is an area of reddened mucosa, within which area there are small patches of more intense congestion and perhaps effusion.

The duodenum presents three considerable patches of what seem to be submucous extravasations. Beside these there are other irregular smaller patches of practically the same character. In addition to the patches of seemingly submucous extravasation in the duodenum, several similar smaller patches are present scattered through the remainder of the small intestine, the jejunum and ileum.

In approximately the upper half of the large intestine the mucosa presents longitudinal reddened streaks, possibly representing submucous extravasations.

The mucosa of the lowermost portion of the rectum, close to the anus, shows marked congestion.

The stomach contained a yellowish flocculent fluid—probably food (milk and eggs). The large gut held a small amount of soft, deep brown fecal matter. One hookworm was found in the region of middle of the jejunum.

The resemblance of the spontaneous to the experimental condition is unmistakable. There are some differences, but with one exception they relate to minor details with respect to which the experimental

disease, as might be expected, affords more definite and fuller information.

The single important exception has to do with the presence of an eruption on the scrotum in some cases of the experimental disease. Such an eruption seems never to have been recorded as occurring in black tongue. Since the eruption by reason of its site may easily be overlooked, we are not inclined to attach any importance to this apparent difference between the two conditions. Indeed, we believe it highly probable that, if sought for, the scrotal dermatitis will be found to occur in the spontaneous disease much as we have observed it in the experimental condition.

Reference should here perhaps also be made to another point of apparent difference, namely, to the commonly held belief, at least up to a few years ago, that black tongue is due to an infection. This view seems to be based mainly on the occasional occurrence of the disease as an epizootic and, in a measure, on the observation that at times after the occurrence of one case in a kennel some, perhaps all, of the other dogs would also be affected. On the other hand, it has quite frequently been observed that the introduction of a case into a kennel is without result so far as the other dogs are concerned and, furthermore, experimental attempts at transmission from sick to well dogs have, with one or two doubtful exceptions, failed (6). The available evidence bearing on the etiology of the spontaneous disease is thus not inconsistent with the possibility of a dietary origin. In this connection we may state that the possibility that our experimental condition is due to an infection was given consideration early in our work, and at our invitation Dr. T. W. Kemmerer, at that time bacteriologist at the Hygienic Laboratory, now director of the State Hygienic Laboratory, Jackson, Miss., very kindly made a culture study (aerobic and anaerobic) of the heart's blood in four cases at necropsy. He reported to us that his results were negative. As our work has progressed and no evidence of communicability of the condition among our animals has at any time appeared and, still more, as we now induce the condition at will by feeding certain diets and can arrest its progress or prevent its occurrence by simple dietary means alone, the idea of an infection as the primary cause of the experimental disease can no longer, it seems to us, be seriously entertained. There being thus no clinical (including post-mortem) or etiological difference between the spontaneous and the experimental conditions to which significance can be attached, it seems permissible to conclude that they are identical.

Relation to the Chittenden-Underhill pellegralike condition in dogs.—As was mentioned in the introductory section of this report, Chittenden and Underhill (3) reported in August, 1917, on "the experimental production in dogs of a pathological condition which closely resembles

in its symptomatology pellagra in the human subject" by feeding a diet of boiled peas, cracker meal, and cottonseed oil. This report appears to be an elaboration of the observation mentioned by Chittenden in his book, The Nutrition of Man, which was quoted in the introductory section of the present communication. The condition produced in the dog by Chittenden and Underhill was described as follows:

> The onset of the pathological symptoms is generally very sudden. Usually the first abnormal manifestation is a refusal to eat, and examination will reveal nothing to account for the loss of appetite. The animal lies quietly in its pen and is apathetic. After continued refusal to eat for a day or two, the mouth of the dog will present a peculiar and characteristic appearance. The inner surface of the cheeks and lips and the edges of the tongue are so covered with pustules as to give the impression of a mass of rotten flesh. The odor from these tissues is foul and almost unbearable. When stroked with absorbent cotton the mucous lining of the mouth comes away in shreds. Intense salivation is present. The teeth appear to be solid and normal. A bloody diarrhea is present, attempts at defecation being very frequent and resulting in the passage of little more than a bloody fluid of foul odor. In some cases the thorax and upper part of the abdomen may contain many pustules half an inch in diameter which are filled with pus organisms. No other skin lesions are prominent. Death usually results without any particularly striking features.
>
> Certain dogs presented symptoms which were not common to all but undoubtedly bear a relationship to the usual manifestations. One animal apparently in the best of health was seized with a convulsion and died in a short time. Another developed the same type of convulsions but lingered for a period of a day, during which convulsions occurred at the rate of every five or six minutes. In the earlier part of this period the animal exhibited a blind, staggering gait, and would run her nose into a wall as though she could not see it. The left eye was closed and twitching, and the left legs were not under complete control, the toes being doubled up. The right side seemed normal. During the latter part of the day the dog lay in a state that appeared to be a mild, continuous spasm. A third dog showed a single convulsion as the initial symptom, and on the following day the characteristic foul mouth and bloody diarrhea were in evidence.
>
> At autopsy two types of conditions are recognizable. In the animals presenting foul mouth and bloody diarrhea the chief interest centers in the lower bowel and rectum which exhibit an intense hemorrhagic appearance. With those animals dying rapidly from convulsions the only visible abnormality of the alimentary tract is the presence in the duodenum of one or more large ulcers.

Allowing for the absence of detail in this description the resemblance to the condition experimentally induced by us and identified as black tongue can hardly fail to arrest attention. The only point of difference which may possibly be significant relates to the skin manifestations which Chittenden and Underhill describe as pustules and are thus quite unlike the pellagralike dermatitis of the scrotum observed in our animals. It is to be noted, however, that Chittenden and Underhill seem to have worked exclusively with females, on the external genitalia of which we have not observed the lesion which occurs on the scrotum of the male. This would explain the

apparent difference in the two conditions. We attach no significance to our failures, referred to in the introductory section, to reproduce the condition by feeding the Chittenden diets.

It is of interest here to note that the resemblance of the Chittenden-Underhill condition to black tongue of dogs was recognized by Carey, of Auburn, Ala., in 1920, and by Wheeler, Goldberger, and Blackstock in 1922 (6).

Considering at this time the similarity of the clinical manifestations alone, it would seem highly probable that the condition induced by us (black tongue) and that produced by Chittenden and Underhill are essentially identical.

RELATION OF EXPERIMENTAL BLACK TONGUE TO PELLAGRA

The resemblance of spontaneous black tongue to human pellagra seems to have attracted the attention of several observers (6). The first to note it appears to have been Spencer, a veterinarian of Concord, N. C., who, in 1916, stated that after studying these two maladies he was "forced to the conclusion that the so-called black tongue is canine pellagra." He gave, however, no details of his studies. Four years later Saunders, a physician of Waco, Tex., suggested that there might be some etiological connection between "sore mouth of dogs" and the human disease. In 1922, impressed by the clinical resemblance, Wheeler, Goldberger, and Blackstock (6) called attention among other things to the strikingly similar geographic distribution of the two conditions in the United States, pointing out that black tongue, like pellagra, seemed to occur principally in the Southern States.

As has already been remarked, the resemblance to pellegra of the experimental condition observed by Chittenden (1) arrested our attention over 12 years ago. This resemblance seems to have struck Chittenden and Underhill at about the same time as it did ourselves, for two years later—that is, in 1917—they published a more detailed account of Chittenden's study and specifically called attention to the resemblance of the condition in the dog to that in the human.

It must be recognized, however, that in all the foregoing the resemblance relates, in the main, simply to the occurrence in both conditions of a disturbance of the digestive tract, notably stomatitis and diarrhea. It seems to us, however, that the resemblance at all events between our experimental condition and pellagra is somewhat more detailed than this. In the first place certain of the characters of the stomatitis, namely the vivid red color, the superficial necrosis with, at times, the formation of a jellylike film or pseudomembrane, are striking features in common. A notable feature or accompaniment of the stomatitis in both conditions is salivation. The two conditions, particularly in the advanced stages,

have in common also a diarrhea which at times is bloody. A paradoxical feature of pellagra, frequently commented on, is the seemingly excellent general state of nutrition observed in many, sometimes even fatal, cases. This is quite characteristic of our experimental condition in the dog. The fever of so-called typhoid pellagra has its analogue, it would seem, in the temperature elevation in the advanced stage of black tongue. All this is striking and suggestive of the identity of the two conditions. More impressive, however, is the occurrence in experimental black tongue of an eruption that in its evolution and certain other distinctive clinical features is indistinguishable from the characteristic dermatitis of pellagra. Taken in conjunction with the other points of similarity to which reference has been made, we believe that the eruption constitutes well-nigh conclusive clinical evidence of the identity of the two conditions, black tongue and pellagra.

Important additional evidence of the identity of these two conditions is found in the suggestion of a common etiology indicated by the successful experimental production of the disease in the dog, as herein above shown, by feeding with a diet of a type found associated with the occurrence of pellagra and also with one previously actually found to be a pellagra-producing diet. Further evidence of a related character pointing to this identity, some of which has elsewhere been already briefly referred to by Goldberger, Wheeler, Lillie, and Rogers (8) will be presented in a later communication.

SUMMARY AND CONCLUSIONS

1. A pathological condition has been induced experimentally in the dog by feeding (*a*) a type of diet observed in association with pellagra and also (*b*) a diet previously found by experimental test in the human subject to be a pellagra-producing diet.

2. A description of the experimental disease summarizing observations extending over a period of nearly five years is presented.

3. The experimental condition is clinically and post mortem indistinguishable from the spontaneous disease of dogs known as black tongue or Stuttgart dog epizootic, and it is concluded that they are identical.

4. On the basis of the similarity of clinical manifestations it is considered highly probable that experimental black tongue and the Chittenden-Underhill pellagralike syndrome in dogs are identical.

5. An eruption restricted to the scrotum occurring in experimental black tongue, which in certain of its distinctive features is indistinguishable from the dermatitis of pellagra, is considered as constituting, at least in conjunction with the other points of resemblance, well-nigh conclusive *clinical* evidence of the identity of the two con-

ditions, black tongue and pellagra. Further evidence to the same effect is found in the suggestion of a common etiology indicated by the successful experimental production of the disease in the dog by feeding with pellagra-producing diets.

Acknowledgments

We desire to express our indebtedness to Surg. Edward Francis, of the United States Public Health Service, for permission to report the results of his feeding experiment in monkeys; to Surg. G. C. Lake, United States Public Health Service, for performing several of the dog necropsies herein recorded; to Drs. Leigh T. Giltner and Jacob E. Shillinger, of the United States Bureau of Animal Industry, and Dr. M. R. Blackstock, veterinarian of Spartanburg, S. C., for valuable aid, freely extended, in the diagnosis of the experimental condition, and to Dr. T. W. Kemmerer, formerly bacteriologist at the Hygienic Laboratory, for generously permitting us to repeat the results of his culture study of the blood of some of our early cases of experimental black tongue.

[1] Computed to represent the average daily consumption per convict volunteer for the two-week period represented by the week ended Aug. 9 and that ended Aug. 29, 1915, as given in Hygienic Laboratory Bull. No. 120, p. 27.

The grits of the prison experiment diet were here replaced by an equal weight of commercial, unbolted corn meal; wheat farina was substituted for wheat flour, sugar for cane sirup, and cabbage for collards.

All of the components were stirred into water and cooked in a double boiler of enamel ware for 1½ to 2 hours.

At the end of this period the cooking was discontinued and the final weight brought to 2,500 grams by the addition of tap water with thorough stirring. Each gram of cooked ration represented approximately 1.2 calories.

At the end of this period the cooking was discontinued, the remaining ingredients were well stirred in and the final weight was brought to 2,000 grams by the addition of tap water. 1 gram of the cooked ration represented approximately 1 calorie.

[2] Its adequacy is indicated by the following experience: Bitch 27 began diet No. 34C on May 17, 1923, early in gestation. On June 26, 1923, whelped a litter of 8 pups which were successfully nursed and weaned in good condition.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Purification of Swimming Baths Water—A Leeds Installation. Anon. *Surveyor,* vol. 72, No. 1865, October 21, 1927, p. 374. (Abstract by R. E. Tarbett.)

A brief article covering the purification plant for the two swimming baths at Holbeck. The combined capacity of the baths is 103,000 gallons The water is circulated through the purification plant once each six hours. It is taken from the deep end of the bath by an electrically driven pump and discharged to the chemical mixing and storage tanks, from which it passes through to 8-feet diameter "pulsometer" pressure filters operated by 172,000 gallons per square feet per hour. The water is heated and aerated before being returned to the pool, aeration being supplied by compressor.

The Water Purification Equipment of the Public Baths of St. Gall. W. Grimm. (Monats -Bull. schweiz. Ver. Gas.-Wasserfach. 1926, No. 5, 7 pp.) In *Chemical Abstracts,* vol. 21, No. 15, August 10, 1927, p. 2519. (Abstract by J. N. Wickert.)

"The pool has a surface of 200 sq. m., a water vol. of 300 cu. m., and accommodates about 61,000 people a year. 50,000 cu. m. a year of the standard drinking water supply is required. It is kept at a temperature of 23.5°. The water is withdrawn from the deep end, passed through a rapid sand filter, chlorinated, and returned to the shallow end. The added water enters with that which has just been chlorinated. The Cl content of the purified water is 0.5 to 0.9 g. per cu. m. The capacity of the filters is 4 times the volume of the tank."

State Regulation of Bathing Places. Arthur M. Crane *Journal American Association for Promotion of Hygiene and Public Baths,* vol. 9, 1927, pp. 30–33. (Abstract by J. L. Robertson.)

The writer notes in discussion of the American Public Health Association report of the joint committee on bathing places that it is quite within the province of duly constituted health authorities to specify a certain degree of purity of pool water and this to be enforced by the police power of the State, but the directions as to how these results may be obtained should not be in the form of an arbitrary rule or regulation subject to penalty. Further comment is made on certain items of the report.

Water Supply and Sewerage for New Australian Capital (**Canberra**). Anon. *Engineering News-Record,* vol. 99, No. 10, September 8, 1927, p. 386. (Abstract by C. G. Gillespie.)

Population is 5,000. Water supply is from Cotter River. Watershed, area 170 square miles, is free of contamination. Average runoff is 70 m. g. d. Water will be stored in a 380 m. g. reservoir, safe yield 7 m. g. d., 15 miles from the city. Raising the dam to 100 feet will increase storage to 1,400 m. g. Water flows by gravity to a motor-driven centrifugal pumping plant, pumping against 840-foot head to a series of three service reservoirs, capacity 1 to 3 m. g. each. Sewage works consist of settling tanks, filters, and activated sludge unit. Experience will determine which system is best for future. Effluent runs to Western Creek, which must be protected against pollution. Treatment works are three miles away on Western Creek.

Bio-aeration Method of Sewage Treatment. H. W. Streeter. *Water Works,* vol. 66, No. 7, July, 1927, pp. 294–295. (Abstract by R. C. Beckett.)

This describes the bio-aeration method of sewage treatment at Sheffield; population, 540,000. Dry weather flow is 18,000,000 gallons; wet weather flow, 65,000,000 gallons. Of the dry weather flow approximately one-third is industrial wastes, such as that from steel mills and breweries. The plant consists of a detritus tank with a capacity of one-thirty-second of the dry weather flow, bar screens with ¾-inch slots and preliminary sedimentation basins of 15,000,000

gallons capacity. Effluent is divided, 10,000,000 gallons to bio-aeration plant, remainder to contact filters. The former consists of eight tanks which connect to Dortmund tanks, thence to final effluent.

Aeration is provided by contact with air on surface by causing sewage to flow through a series of parallel channels each 6 feet wide and 4 feet deep at a velocity of 1½ feet per second, and agitating the surface layers by overhung paddle wheels extended across the width of the channels.

The effluent is colorless and odorless, having a high relative stability and a bacterial content of about 50,000 colonies per c. c. The power consumption is estimated from 30 to 35 h. p. per million gallons. Cost of operation, 2 pence 18 shillings per million gallons, d. w. f. Cost of construction from 25,000 pounds to 30,000 pounds per million gallons, d. w. f.

The disposal of sludge is yet unsolved.

The Treatment of Sewage by Activated Sludge. Anon. *Annales d'Hygiene Publique, Industrielle et Sociale*, vol. IV, No. 12, December, 1926, p. 732. (Abstract by R. C. Beckett.)

The author, after a survey of the literature, concludes that the activated sludge process is of bacterial origin. The quantity of activated sludge must be proportioned to the consumption of the organic matter of the liquid, to the nature of these, to aeration, to the condition of the sludge, and to temperature.

It is necessary to aerate sufficiently to maintain the best bacterial flora, and to proportion the aeration to the activity of the bacteria, to the quantity of organic material to be acted on, and to the quantity of sludge in order not to pass the moment when the sludge itself is altered and commences to putrefy. The sludge should be settled well and should retain but little of the suspended solids.

Court Ruling on Erection of City Sewage Disposal Plant. Anon. *Water Works*, vol. 66, No. 7, July, 1927, p. 265. (Abstract by R. C. Beckett.)

The Texas Court of Civil Appeals in the case of Boyd et al. *v.* City of San Antonio, Texas, decided against the issuance of an injunction which would have prevented construction of sewage disposal plant on a site 2½ miles from the city limits, holding that the convenience of the public outweighed the damage done to any one individual.

It further held that evidence was insufficient to show that a nuisance would result; but if it did, the individual still had his remedy at law after the plant was in operation.

Separate Sludge Digestion. L. Siebert. Proceedings of the First Conference of Sewage Works Operators, Pennsylvania State College Bulletin No. 1, January, 1927, pp. 21–30. (Abstract by L. F. Warrick.)

The author presents an interesting historical outline of sewage treatment leading up to separate sludge digestion. This process provides for settlement of solids in one tank, with removal of scum and sludge therefrom at sufficiently frequent intervals to prevent the troublesome disturbances of septic action, to separate entirely sludge digestion tanks. Sewage settling tanks used are classed as (1) gravity, and (2) mechanical types. Most economical construction in the first case calls for a relatively small, square tank with a single hopper, the slope of which is 2 to 1, or about 63 degrees from the horizontal. The mechanical type of tank is that equipped with Dorr clarifier, link belt, or similar mechanism for positive removal of sludge. The design and operation of such equipment is briefly described.

Shortcomings of separate sludge digestion systems and some suggested remedies are summarized as follows: (1) Ineffective removal of settleable solids from septic action in settling tanks, due primarily to faulty design; (2) formation of scum

instead of sludge in the digestion tanks. Adjustment of pH to 7.3–7.6 with lime and de-watering the digestion tank are corrective measures; (3) lack of capacity for sludge digestion, which may be eliminated by de-watering facilities; (4) retarded or suspended sludge digestion, generally overcome by covering, and in some cases, by heating the tank; (5) cost of operation somewhat greater than Imhoff tanks.

Advantages are listed as follows: (1) Economy of construction cost as against the cost of Imhoff tanks, particularly where deep excavation is exceptionally expensive; (2) ability to accomplish efficient removal of settleable solids and production of a good sludge capable of easy drying; (3) flexibility in the relation of settling capacity to digestion capacity, since one may be increased without the necessity of increasing the other, which may be adequate; (4) more positive control over the operation and functioning of the separate units of the plant than in Imhoff tanks or other systems; (5) applicability of separate sludge digestion tanks as additions to Imhoff tank installations in which the sludge digestion capacity is insufficient but the settling capacity is adequate.

The Septic Tank—Its Function and Operation. Raymond O'Donnell. Proceedings of the First Conference of Sewage Works Operators, Pennsylvania State College Bulletin No. 1, January ,1927, pp. 7–9. (Abstract by L. F. Warrick.)

The author describes in a concise manner septic tank treatment of sewage under the headings of function, definitions, character of applied sewage, constructional features, operation, scum, and sludge. Removal of suspended matter by sedimentation and digestion of organic matter so removed constitute the functions of a septic tank. A successfully operating tank will probably remove 50 to 60 per cent of the settleable solids of separate sewage and reduce the volume of these by. gasification, liquefaction, and solidification to between 50 and 70 per cent of their original volume. Oversepticization is very detrimental to oxidation on filters or contact beds, while undersepticization produces excessive amounts of sludge. In cleaning a properly functioning tank, it is well to leave some sludge as seed for future operation. A vile, odoriferous sludge can generally be improved by removing a tank from service for six weeks, which in effect is separate sludge digestion.

New Water Softening Plant for Beverly Hills, California. R. L. Derby, *Western Construction News*, vol. 2, No. 20, October 25, 1927, pp. 31–34. (Abstract by E. A. Reinke.)

Beverly Hills derives its water supply from various wells averaging 15 or 16 grains per gallon hardness and 8 or 10 p. p. m. hydrogen sulphide. Treated water will not be over 3 grains hardness, and sulphides will be practically eliminated. After experimental work on a 70,000 g. p. d. plant a 5 m. g. d. plant was designed to include: (1) aeration; (2) coagulation with lime and alum; (3) sedimentation; (4) secondary alum coagulation; (5) secondary sedimentation; (6) filtration. Chlorination is provided to be added at any point after aeration. It will probably be used after secondary sedimentation. Aeration will remove 40 to 60 per cent of the hydrogen sulphide. The aeration house is covered and closed on the east and north, the southand west being open to take advantage of trade winds. In the northeast corner is a ventilating tower 118 feet high, with a 6-foot stack provided with an oil burner at the base. At the present plant no nuisance is noted with a 60-foot stack and none is expected in the new plant. Primary coagulation tanks with motor-driven mixing paddles are followed by a Dorr clarifier with 60-minute retention period. The water then flows through secondary coagulation tanks similar to the primary tanks and then to 2 sedimentation basins with 5 hours' retention period. Split alum dosage and long retention has been found economical and permits the greatest reduction of hydrogen sulphide. Five filter units of 1. m. g. d. each are provided, and the

design allows for five additional units on the opposite side of the pipe gallery. Red brass tube underdrains of the perforated pipe type are used and provision is made for air wash. The chlorinating apparatus is housed in a separate room with outside entrance. The clear water reservoir has a capacity of 5,000,000 gallons.

The Upper San Leandro Filtration Plant of the East Bay Water Company, Oakland, California. Wilfred F. Langelier. *Western Construction News*, vol. 2, No. 19, October 10, 1927, pp. 77–83. (Abstract by E. A. Reinke.)

The Upper San Leandro filtration plant is a thoroughly modern plant of 12 m. g. d. capacity, designed to handle the supply from Upper San Leandro Reservoir. In addition to high turbidity and color at certain seasons, traces of manganese were expected in the raw water, as had been found at the neighboring San Pablo plant, where it badly coated the sand grains and impaired the efficiency of filter units.

The plant consists of nozzle aerators; 4 coagulation units, each 20 feet in diameter by 20 feet deep, with motor operated stirring mechanisms; sedimentation basins of 2,000,000 gallons capacity arranged in duplicate for series or parallel flow and for double coagulation; four 3 m. g. d. filter units, bifurcated so that half units may be washed; chlorinators for treating raw and filtered waters; a 3,000,000 gallon filtered water storage reservoir; and provision for recovery of wash water.

Unusual features of the plant include, coarse Monterey beach sand (E. S. = 0.40 m. m.; U. C. = 1.7) to avoid manganese incrustation; use of red brass tubing for perforated pipe underdrains; use of air wash with high rate water wash to prevent incrustation of sand grains with manganese, simplified pipe gallery well lighted and drained and with all controls at a central table from which all four filters can be run by operator; chlorinators in rooms with outside entrances, but windows to allow operator to see these from inside, and use of one-ton cylinders of chlorine. The whole plant is designed and landscaped to give a pleasing appearance.

Milk-Borne Disease in Massachusetts. George H. Bigelow and Filip C. Forsbeck. *American Journal Public Health*, vol 17, No. 10, October, 1927, pp. 1019–1023. (Abstract by R. E. Irwin.)

"Questionnaires were sent to the 70 cities and towns of 10,000 population and over, and replies were received from 44. The population of the towns from which we received information is 70.2 per cent of the total population of the state."

In 11 tables the data for the past three years are tabulated with comparative figures from the previous reports, when these are available.

The information given in the tables as well as the summary and conclusions are worthy of careful study by those interested in statistics relating to milk-borne diseases, dairy inspections, and milk consumption. The authors emphasize the fact that "it should be stressed that the vulnerability of a milk supply is more accurately estimated by the number of outbreaks for which it is responsible than by the total number of cases."

Some Variations of the Heat Method for Sterilizing Milking Machines. L. H. Burgwald. *Journal Agriculture Research*, Washington, 1927, vol. 34, 27–33. Abstract by W. G. Savage in the *Bulletin of Hygiene*, vol. 2, No. 9, September, 1927, p. 730.

"Earlier workers found that heat sterilization methods gave excellent bacteriological results, but were destructive to certain of the rubber parts. The author carried out a further series of tests, judging the efficiency of the sterilization by the bacterial content of the milk obtained after the use of the milking machines. Very low counts were obtained when the units of the machine were heated in water at a temperature of 160° to 167° F. for 20 to 35 minutes, and then either

removed to a refrigerator or placed in a weak chlorine solution (about 1:20,000) between milkings. The life of the rubber parts was materially longer than when the units were allowed to remain in the hot water between milkings. A cold place (below 50° F.), if protected from contamination, gave nearly as good results as placing in a refrigerator. A lower temperature for the hot water, i. e., 145° to 150° F. gave longer life for the rubber parts, but the bacterial counts were not nearly as low as when the higher temperature was adopted. Any form of heat sterilization, however, shortened the life of the rubber parts more than salt or chlorine methods. The teatcup linings always perished first."

Various Antimalaria Organizations in Italy. B. Gosio., Provveditorato Generale Dello Stato Libreria, Rome. 1925. 180 pages. (Abstract by M. A. Barber.)

A description of malaria prevention activities now in operation in Italy. The scope of the work is indicated by the following topics:

Training school for malaria workers. A short and intensive course in the practical application of antimalaria measures is provided for those who are to give all or a part of their time to such work. The length of the course varies with the class of persons to be instructed: For physicians a few conferences and demonstrations may suffice; for less instructed persons, a period of 10 or 15 days.

Instruction of school children in malaria prevention. The work includes not only instruction in hygiene, but the practical application of hygienic measures—the establishment, in schools, of baths, heliotherapy, and other means for the cure of disease and preservation of health.

Ambulatory service, in which a personnel skilled in malaria work may move from place to place, instructing the people, curing the sick, and eliminating carriers. Sometimes units are provided only with a pack horse or horse and cart. A unit may be mobile, visiting sparsely populated districts or following migratory laborers; in localities more densely populated, units may remain for long periods of time. Diseases other than malaria may receive attention.

Colonies where malaria-infected children are assembled for treatment. Ordinary as well as hygienic instruction is provided for.

A warehouse where supplies of all sorts needed in malaria work are kept in stock.

Malaria research. In the chapters devoted to this topic Professor Gosio and Dr. A. Missiroli give many interesting details regarding malaria-control measures. They describe in full methods of studying the habits of the larvae and adults of mosquitoes and give a list of the aquatic plants which favor or discourage the development of larvae. No species of *Chara* was found which hinders the growth of anopheline larvae in that climate, at least during the season when they were studied. On the other hand, duckweed (*Lemna*), the action of which is only mechanical, asphyxiating larvae, has proved a useful measure in some localities, as in the valley of the Po. Among larvicides, Paris green has proved to be successful. Methods of drainage and types of drainage tile are described fully. *Gambusia*, introduced into Italy, has thrived there and become a useful ally in mosquito destruction. The apparatus and chemicals suited for killing mosquitoes in houses and stables are illustrated and described Domestic animals may prove useful in attracting Anopheles to stables where they may be captured or destroyed.

The book is well illustrated and not only describes the scope of antimalaria organizations in Italy, but also serves as a useful handbook for malaria workers.

Studies on Brazilian Mosquitoes. II. Chagasia fajardoi. Francis Metcalf Root. *American Journal of Hygiene*, vol. 7, No. 4, July, 1927, pp. 470–480. (Abstract by M. A. Barber.)

A description, fully illustrated, of the Brazilian anopheline, *Chagasia fajardoi*. The larvae of this species are found in rapid current streams, and, as in Oriental current breeders, their grappling tail hairs have more, stronger, and more decidedly hooked branches than do those of larvae which frequent quiet waters. The adult has a *Culex*-like resting attitude.

Malaria in Haiti. C. S. Butler and E. Peterson. *United States Naval Medical Bulletin*, vol. 25, No. 2, April, 1927, pp. 278–288. (Abstract by L. L. Williams, jr.)

This brief article is a very clear picture of the high points of malaria in Haiti, and a good description of the island in relation to mosquito production. Haiti has only one efficient vector of malaria, *A. albimanus*. This anopheline is capable of transmitting all three types of malaria. The authors give their reasons for believing that malaria was imported into Haiti and is not of native origin.

The island is small, having but 10,200 square miles, less in area than the State of Maryland; yet it has various kinds of climate—from tropical on the coast to temperate in the hills. The most important plateau is a large central plain, approximately 1,200 square miles in area. Parts of the island are desert-like in their dryness; other portions are exceptionally wet. Late summer and winter are the malarial seasons. *Albimanus* breeds in all sections of the island, wherever water collects and has been found up to 2,500 feet above sea level. Rainfall varies in different parts of the island from a minimum average of 21.7 inches annually (portion of the island where the runoff dries quickly, nonmalarious) to 167 inches in the most malarial part.

Malaria is very prevalent and severe. Splenic index in a large number of school children shows rates varying from a minimum of around 2 per cent to a maximum of 100 per cent. Many schools show rates between 20 per cent and 60 per cent.

The problem of control differs in type in the rural and urban centers. It is the authors' belief that rural districts must at present depend solely upon adequate quinine treatment of those sick. Many of the cities practice mosquito control, and it is advised that the remainder of them initiate its practice.

A. albimanus quickly commences breeding in new swampy places formed by heavy rains, thus differing from our *quadrimaculatus*. The malaria infection very closely follows the rainfall, lagging behind about two months.

Control work at Port au Prince is described in a general outline. It was an extensive piece of work. *Albimanus* was breeding in many of the street ditches in seepage areas, and the nearby extensive swamps. For the ditch breeding and the seepage, the attack was drainage and fill. Rock drains (earth covered) were used extensively with success. Much of the swamp land was dried by complete clearing of brush and opening it up to process of evaporation. Some of the swamps were drained, and low portions were filled. Apparently the major portion of the work has now been completed, but there is yet some which remains to do. The tables giving malaria infection by months for a number of years show a steady decline in the case rates from a January rate (1924) of 1,350 per thousand to the January rate (1926) of only 125 per thousand.

Oiling as a Remedy for Malaria. Anon. *All India Local and Municipal Self-Govt. Gazette*, vol. 14, No. 4, March 14, 1927, pp. 71–72. (Abstract by L. L. Williams, jr.)

This is a brief article in popular style designed for education of the citizenry on how to oil, where to oil, and when to oil. Warning is given against "submerged bundles" and "drip cans." The author says "Try it and see! It is a lazy way of doing antimalaria work; it is like wanting something for nothing."

Use of the spray can is described, and the care of the pump is stressed. Good outline is given on how to train Hindu workers as oilers. Use of a fine spray is stressed. The worker is compelled to walk in the ditch and is directed to walk rapidly while spraying.

DEATHS DURING WEEK ENDED JANUARY 14, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended January 14, 1928, and corresponding week of 1927. (From the Weekly Health Index, January 19, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended Jan. 14, 1928	Corresponding week, 1927
Policies in force	69, 954, 836	66, 596, 510
Number of death claims	15, 439	13, 673
Death claims per 1,000 policies in force, annual rate	11. 5	10. 7

Deaths from all causes in certain large cities of the United States during the week ended January 14, 1928, infant mortality, annual death rate, and comparison with corresponding week of 1927. (From the Weekly Health Index, January 19, 1928, issued by the Bureau of the Census, Department of Commerce)

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 96 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 30,910,000. The estimated population of the 92 cities reporting deaths is more than 30,330,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended January 7, 1928, and January 8, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
42 States	2,084	2,302	
96 cities	1,008	1,151	1,137
Measles:			
40 States	7,362	9,195	
96 cities	3,077	2,242	
Poliomyelitis:			
42 States	60	20	
Scarlet fever:			
42 States	3,774	5,329	
96 cities	1,216	1,861	1,332
Smallpox:			
42 States	867	799	
96 cities	100	114	81
Typhoid fever:			
42 States	215	342	
96 cities	28	48	45
Deaths reported			
Influenza and pneumonia:			
92 cities	1,101	1,215	
Smallpox:			
92 cities	0	0	

City reports for week ended January 7, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence if epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during non-epidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

[1] Rabies (human): 1 case and 1 death at Chicago, Ill., and 1 death at Richmond, Va.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended January 7, 1928, compared with those for a like period ended January 8, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, December 4, 1927, to January 7, 1928—Annual rates per 100,000 population, compared with rates for the corresponding period of 1926–27 [1]

FOREIGN AND INSULAR

PLAGUE RATS ON VESSEL

Steamship "Modemi"—At Goteborg, Sweden—From Bahia and Buenos Aires—Under date of December 29, 1927, the arrival of the steamship *Modemi* from Bahia and Buenos Aires, with a cargo of grain, was reported at Goteborg, Sweden. Dead rats were found on board, but no plague was shown to exist at time of fumigation of the vessel. On December 22, 1927, plague indications were reported found among rats. The *Modemi* left Buenos Aires November 11 and St. Vincent, Cape Verde Islands, December 1, 1927.

ARGENTINA

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported at Rosario, Argentina, as follows:

Disease	Cases	Disease	Cases
Diphtheria	3	Scarlet fever	7
Gastroenteritis	33	Tuberculosis	17
Measles	2	Typhoid fever	2
Meningitis	21	Typhus fever	1
Plague	1		

Population, estimated, 419,487.

BARBADOS (BRITISH WEST INDIES)

Further[1] *relative to outbreak of malarial fever.*—Further information, under date of December 23, 1927, relative to the outbreak of malarial fever reported at Barbados, British West Indies, shows the disease prevalent in all parts of the island, with 930 reported cases. Of this number, 296 cases were stated to have occurred in the parish of St. James. To December 20, 21 deaths from the disease were reported. The fatalities were stated to have been among the aged.

BELGIAN CONGO

Yellow fever—Boma and Matadi—Kongo River ports—January 3, 1928.—Under date of January 3, 1928, seven cases of yellow fever were reported for the ports of Boma and Matadi, on the Kongo River, Belgian Kongo.

[1] Public Health Reports, Jan. 20, 1927, p. 152.

CANADA

Communicable diseases—Ontario—December, 1927—Comparative.—During the month of December, 1927, communicable diseases were reported in the Province of Ontario, Canada, as follows:

Disease	1927		1926	
	Cases	Deaths	Cases	Deaths
Cerebrospinal meningitis	2	1		3
Chancroid	1		1	
Chicken pox	1,306		1,247

Typhoid fever	867	35	581	32
Whooping cough	5, 526	29	3, 679	67

Communicable diseases—Quebec—Week ended January 7, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended January 7, 1928, as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	1	Scarlet fever	108
Chicken pox	34	Smallpox	6
Diphtheria	66	Tuberculosis	13
German measles	11	Typhoid fever	4
Influenza	3	Whooping cough	4
Measles	100		

CANARY ISLANDS

Plague—Las Palmas.—A case of plague was reported at Las Palmas, Canary Islands, December 16, 1927.

CHILE

Campaign for prevention of tuberculosis—Housing and sanitary conditions.—Under date of November 2, 1927, the press in Chile was stated to be conducting a campaign for the prevention of tuberculosis through improvement in housing and sanitary conditions for the poorer classes.

CUBA

Communicable diseases—Provinces—October 2–December 24, 1927.—During the period from October 2 to December 24, 1927, cases of communicable diseases were reported from the provinces of Cuba as follows:

Disease	Pinar del Rio	Habana	Matanzas	Santa Clara	Camaguey	Oriente	Total
Chicken pox		18	8	4		7	37
Diphtheria	5	23	25	22	8	8	91
Malaria	20	208	2	13	334	1, 447	2, 024
Measles	8	46	7	3	24	1	89
Paratyphoid fever	17	9	5	20	1	3	55
Poliomyelitis	1						1
Scarlet fever		8	1				9
Tetanus (infantile)			1		1		2
Typhoid fever	51	188	52	120	25	93	529

EGYPT

Plague—Alexandria—December 14, 1927.—On December 14, 1927, two cases of plague occurring in the same family were reported at Alexandria, Egypt. The focus of the disease was stated to be distant about 700 meters from the port and about 500 meters from the house in which the first case occurred.[1]

HAWAII TERRITORY

Plague rats—Paauhau—December 20, 1927.—Two plague-infected rats were reported found dead on the Paauhau sugar plantation, Paauhau, Hamakua, Island of Hawaii, December 20, 1927.

JAMAICA

Smallpox (alastrim)—November 27-December 31, 1927.—During the period November 27 to December 31, 1927, four cases of smallpox, reported as alastrim, were reported in the Island of Jamaica, occurring in localities not included in the Kingston area.

Other communicable diseases.—During the same period other communicable diseases were reported in the Island as follows:

Cases

Disease	Kingston	Other localities	Disease	Kingston	Other localities
Chicken pox		11	Poliomyelitis		1
Diphtheria		1	Puerperal fever		3
Dysentery	8	7	Tuberculosis	35	38
Erysipelas		1	Typhoid fever	39	99
Leprosy		1			

Population Island 926 000 Kingston 62 707

JAPAN

Dysentery—Tokyo, city and prefecture—October 30-November 26, 1927.—During the period October 30 to November 26, 1927, 144 cases of dysentery with 71 deaths were reported in the city of Tokyo, Japan, and 149 cases with 83 deaths in the prefecture of Tokyo, outside of the city. Population of city, 1,995,567; prefecture, outside of city, 2,489,577.

MADAGASCAR

Plague—October 1-15, 1927.—During the two-week period, October 1 to 15, 1927, 63 cases of plague with 59 deaths were reported in the island of Madagascar. The occurrence was reported in four Provinces as follows: Ambositra, 4 cases; Antisirabe, 2; Itasy, 5; Moramanga, 4; Tananarive, 48. Distribution by type of disease: Bubonic, 37; pneumonic, 2; septicemic, 24.

PERU

Mortality, general—Mortality from communicable diseases—Lima city—October, 1927.—During the month of October, 1927, 385 deaths from all causes were reported in the city of Lima, Peru. Mortality from communicable diseases during the same period was reported as follows:

Disease	Deaths	Disease	Deaths
Cerebrospinal meningitis	9	Plague	1
Gastroenteritis	38	Tuberculosis	91
Influenza	7	Typhoid fever	5
Malaria	8		

Population, estimated, 196,767.

SALVADOR

Mortality, general—Mortality from communicable diseases—July–September, 1927.—During the three months ended September 30, 1927, 7,604 deaths from all causes were reported in the Republic of Salvador. Deaths from communicable diseases were reported as follows:

Disease	Deaths	Disease	Deaths
Diphtheria	4	Tuberculosis	174
Gastroenteritis	210	Typhoid fever	11
Measles	54		

Population, 1,600,000.

Prevailing diseases.—The diseases prevalent in the Republic during the period under report were stated to be intestinal disorders and malarial and other tropical fevers.

TRINIDAD

Vital statistics—Port-of-Spain—November, 1927.—The following statistics for the month of November, 1927, with comparisons for November of the years 1923 to 1926, are taken from a report issued by the Public Health Department of Port-of-Spain:

Month of November

	1923	1924	1925	1926	1927
Number of births	170	142	146	176	186
Births per 1,000 population	32.77	27.38	27.78	33.18	34.81
Number of deaths	126	124	132	126	118
Deaths per 1,000 population	24.29	23.91	25.11	23.75	22.08
Deaths under 1 year	21	26	25	24	17
Deaths under 1 year per 1,000 births	123.53	183.09	171.23	136.36	91.39

Cases of communicable diseases reported during November, 1927

	Cases		Cases
Diphtheria	3	Tuberculosis, pulmonary	10
Ophthalmia neonatorum	8	Typhoid fever	7
Pneumonia	3		

UNION OF SOUTH AFRICA

Plague—Orange Free State.—An outbreak of plague was reported in the Winburg District of the Orange Free State, Union of South Africa, during the week ended November 26, 1927, with 8 cases and 6 deaths. The outbreak occurred on a farm.

TREASURY DEPARTMENT

PUBLIC HEALTH REPORTS

ISSUED WEEKLY

BY THE UNITED STATES
PUBLIC HEALTH SERVICE

VOLUME 43 :: :: NUMBER 5

FEBRUARY 3 - - 1928

SPECIAL ARTICLES

Prevalence of Influenza in the United States

Tularaemia among Meadow Mice in California

Reports of the Health Section, League of Nations

UNITED STATES
GOVERNMENT PRINTING OFFICE
WASHINGTON
1928

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

Asst. Surg. Gen. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests

ADDITIONAL COPIES
OF THIS PUBLICATION MAY BE PROCURED FROM
THE SUPERINTENDENT OF DOCUMENTS
U. S. GOVERNMENT PRINTING OFFICE

PUBLIC HEALTH REPORTS

VOL. 43 FEBRUARY 3, 1928 NO. 5

PREVALENCE OF INFLUENZA IN THE UNITED STATES

During the year 1927 comparatively few cases of influenza were reported. During the first four months of the year the contrast with the corresponding period of 1926 was marked.

The following table gives the number of cases of influenza as reported by 28 States for 52 weeks of the years 1925, 1926, and 1927:

Cases of influenza reported by 28 States for 52 weeks

	Cases
[illegible]	[illegible]
1926	110, 494
1927	36, 373

The estimated population of these States in 1927 was 62,771,000. At the close of the year the comparison is not so favorable for the year 1927, although there are no indications of any unusual prevalence of influenza. The following table gives, by four-week periods, the numbers of cases reported by the health officers of 28 States for the last 20 weeks of the years 1925, 1926, and 1927:

Influenza cases reported by four-week periods for the last 20 weeks of years 1925, 1926, and 1927

Four weeks ended—	Corresponding weeks—		
	1927	1926	1925
Sept. 10, 1927	629	683	495
Oct. 8, 1927	777	966	569
Nov. 5, 1927	1, 429	2, 087	1, 559
Dec. 5, 1927	2, 022	2, 446	2, 256
Dec. 31, 1927	3, 035	2, 946	3, 015
Total	7, 892	9, 128	7, 894

The death rates from influenza and pneumonia, all forms (combined), during the 10-year period from 1917 to 1926, inclusive, in the registration area, were as follows:

Death rates per 100,000 from pneumonia, all forms, and influenza (combined) in the registration area

1917	167. 8	1922	133. 5
1918	537. 0	1923	153. 7
1919	222. 3	1924	117. 7
1920	208. 3	1925	123. 1
1921	99. 8	1926	143. 2

TULARAEMIA AMONG MEADOW MICE (*Microtus californicus aestuarinus*) IN CALIFORNIA

By J. C. PERRY, *Senior Surgeon, United States Public Health Service*

During September, 1927, Messrs. Stanley E. Piper and W. P. Garlough, of the United States Biological Survey, while investigating conditions in a selected area in Contra Costa County, Calif., preliminary to placing thalium poison for squirrel eradication, noted that there was a heavy infestation with both wood rats and meadow mice (*Microtus californicus aestuarinus*) and that some epidemic disease existed among the mice, as large numbers of dead and sick mice were found. These men were familiar with the migration and disease in the meadow mice that occurred in Kern County, Calif., in 1926, as well as with the bacteriological findings of Surg. N. E. Wayson [1] in his investigation of that disease. They thought that probably the same disease found in the mice in Kern County was responsible for the mortality noted among those in Contra Costa County and that it would be of value and interest to determine whether this was true or whether some other disease was the responsible factor.

An inquiry was made as to whether the United States Public Health Service plague laboratory at San Francisco would undertake the examination of some of these mice, and upon being answered that it would do so, two mice were sent to the laboratory on September 24, 1927.

Upon dissection, these mice showed no gross pathological lesions and none of the appearances noted in mice dying from mouse septicemia. However, smears from the spleen showed numerous thin, short bacilli that presented the appearances of *Bacterium tularense*.

Inoculations of animals were made by grinding up the spleens of the mice and using a portion of this material subcutaneously. Two white mice and one white rat were inoculated from each of the original wild mice. Therefore, two series of experiments were run and may be designated as first and second series. At the same time, September 24, inoculations were made from the spleens on agar plates.

FIRST SERIES

The two white mice and the rat inoculated on September 24 died on September 26. There was some subcutaneous fluid at point of inoculation, but no morbid changes were seen in the spleen, liver, or lungs. The absence of gross pathological lesions was probably due to the early death of the animals. Microscopic preparations made from the subcutaneous fluid showed numerous small organisms like

[1] Wayson, N. E. An epizootic among meadow mice in California, caused by the bacillus of mouse septicemia or of swine erysipelas. Pub. Health Rep., 42: 1489-1493, (June 3) 1927.

those seen in smears from the wild mice. This fluid was plated on plain agar, but no growth of the thin, short rods occurred.

On September 26, two guinea pigs were inoculated from the spleen of one of the wild mice. One inoculation was subcutaneous and the other was pocketed.

SECOND SERIES

The white mice inoculated on September 24 from the second wild mouse died on September 28. Their spleens were enlarged, dark in color, and quite firm. The lymphatic glands were enlarged. Liver and spleen were not stippled. Many organisms of the same type as previously mentioned were found in microscopic preparations made from the spleen and enlarged glands. The rat was killed on September 30. Its spleen was slightly enlarged and firm, and showed some white punctate spots (stippling). Smears of the spleen showed thin, short rods.

Two guinea pigs were inoculated from the spleen and glands of a white mouse of the second series that died on September 28.

GUINEA PIGS

The pigs inoculated on September 26 from the spleen of one of the wild mice died on October 6, living nine days. The pigs (second series) inoculated on September 28 died on October 4 and 5, respectively.

The gross pathological findings were the same in all four pigs. The spleens were enlarged, dark in color, and finely studded with small, white punctate spots (markedly stippled). The livers were also stippled. The lesions were typical of tularaemia.

CULTURES

As no growth had occurred on ordinary culture media, cultures were made on coagulated egg yolk medium from the spleens of the guinea pigs that died on October 5. A pearly growth occurred on this medium, which conformed in morphological and cultural characteristics to that of a strain of *Bacterium tularense* which has been maintained in the laboratory since 1919.

Two guinea pigs were inoculated from these cultures on October 12, one of which was killed on October 17 while very sick and the other died the following day. The gross lesions in the pigs inoculated with cultures were the same as those noted above in pigs which had been inoculated with mouse tissue.

Cultures obtained from the spleen of the pig that died October 18 bore the morphological and cultural characteristics of *Bacterium tularense*.

DISCUSSION

The demonstration of tularaemia in the meadow mice submitted was effected by careful observance of laboratory procedure. Upon dissection they showed no gross morbid changes and might have been discarded by a less trained worker than the technician in this laboratory, who is familiar with both tularaemia and mouse septicemia, including both the pathology and bacteriology of these diseases. Credit is due Michael Burkel, the laboratory technician, for excellent work in carrying out this investigation under the direction of the writer.

Pigs inoculated with this strain often die in six or seven days. However, animals inoculated by simply rubbing the diseased spleen on a scarified area will live several days longer than when the inoculation is made from material of the ground spleen. One pig inoculated by the former method lived 14 days.

Guinea pigs that live 10 or 14 days are more likely to show lung lesions of tularaemia, and the one of our series that lived 14 days showed the entire lungs studded with white spots. No stippling was noted in the lungs of any of the other pigs

The spleens of the inoculated guinea pigs may be firm, almost granular on maceration, or softened. This seems independent of the length of time the pig lives, and occurred in equal proportion in our series.

It was noted in isolating cultures that material secured by searing the surface of the spleen and passing a loop through this area very often did not result in any growth; but when ground spleen pulp was used as an inoculum, the surface of the spleen having been previously sterilized by dropping it into boiling water, satisfactory results followed.

It was noted that a much larger number of organisms was present in smears made from the spleens of mice than in those made from the spleens of rats and guinea pigs. This held equally true for the wild mice and the white mice in the laboratory.

Meadow mice harbor mites. This was noted in the examination of those from Kern County, Calif., in 1926; and since the mice migrate for food and live together in nests, transmission of tularaemia among them by mites is probable.

SUMMARY

Two meadow mice (*Microtus californicus estuarinus*) collected in nature in Contra Costa County, Calif., where large numbers of sick and dead mice were found, were sent to the United States Public Health Service plague laboratory in San Francisco for examination on September 24, 1927. Spleens of the wild mice were inoculated into

white mice, white rats, and guinea pigs, causing the typical lesions of tularaemia, and from the latter *Bacterium tularense* was isolated. The organism was a slender, short rod, Gram-negative, nonmotile, and grew only on coagulated egg yolk and blood glucose cystine agar, and not on ordinary plain agar. It was agglutinated out to the full anti-*tularense* titre (1:1280) of a known anti-*tularense* serum. Sections of the liver of infected white mice showed the hepatic cells packed with these organisms. Spleen tissue rubbed on the abraded skin of a guinea pig caused its death with the typical lesions of tularaemia—caseous lymph glands, spotted spleen, and spotted liver.

This is the first record of *Bacterium tularense* having been isolated from naturally infected wild mice.

CURRENT PREVALENCE OF DISEASE

REVIEW OF THE MONTHLY EPIDEMIOLOGICAL REPORT OF THE HEALTH SECTION OF THE LEAGUE OF NATIONS' SECRETARIAT, PUBLISHED AT GENEVA, DECEMBER 15, 1927 [1]

Plague.—Only sporadic cases of plague were reported during the autumn months in the Mediterranean area. In Egypt, no case was reported from September 11 to November 12; in the following two weeks, five cases occurred at Alexandria.

No case of plague had been reported from Syria since September 17. No plague was reported from Tunisia between August 7 and November 20. In Algeria, 1 plague case was reported at Algiers and 2 cases were reported at Oran during the first 5 days of November; an additional case was reported at Oran on November 17.

In Greece, plague cases occurred in only two centers—at Patras and Plomarion on the island of Mytilene (Lesbos). There were 2 cases at Patras in September and 3 cases in November; at Plomarion there were 6 cases in September, 3 in October, 3 in November, and 1 on December 1. A Greek steamer was sent to the quarantine station at Vigo, in Spain, on November 19, three plague cases having occurred on board.

Two cases of pneumonic plague occurred on November 30 at Las Palmas on the Canary Islands.

Plague incidence was declining during September and October, or was lower than in preceding months, in Kenya, Nigeria, Uganda, and Senegal. In Uganda, the cases reported in 1927 up to October 15 numbered 1,908, which is more than were reported in any of the preceding five years, but a much lower number than was reported in 1921.

[1] From the Office of Statistical Investigations.

October returns from Madagascar (166 cases) were lower than for the corresponding month of the preceding two years; the seasonal maximum usually is reached in December or January. In the Union of South Africa three cases of plague were reported between October 16 and November 19 on inland farms.

Plague incidence in India up to the end of October had been much lower than the mean incidence in preceding years. The incidence in the various provinces of India is described in the Report (a monthly publication), as follows:

> Excluding Burma, no plague has been reported anywhere east of Azamgarh in the United Provinces. During the nine weeks ended October 15, there were 33 deaths attributed to plague in the United Provinces and 33 in the Punjab, inclusive of native States; the corresponding figures for 1926, which was also a very favorable year, were 104 and 306, respectively. During the nine weeks, 192 deaths from plague were reported in the Central Provinces, as compared with 932 during the corresponding period of the preceding year. The incidence is lower than last year in Hyderabad and Mysore, and about the same in the Bombay and Madras Presidencies. Plague is usually at its maximum in September or October in the Deccan, but during the week ended October 15 there was a marked increase of plague in the Districts of Dharwar and Satara in the Bombay Presidency. Weekly returns of plague deaths in Burma have constantly been between 20 and 40 since July.

In Siam, 24 plague cases were reported in the first 10 months of 1927, of which 9 occurred at Bangkok. During the same period, 73 cases were reported in Cambodia, 17 in Cochin-China, and none elsewhere in French Indo-China.

No plague case had been reported from any Chinese port since early in August, when plague was present at Amoy.

The Argentine Republic reported cases of plague as occurring in several inland localities. Ten cases were reported at the end of October in the Province of Cordoba with another case in the latter part of November; 1 case was reported on November 14 near Bahia Blanca, and 1 case on November 26 at Rosario.

In Peru, fewer cases of plague were reported during the first 9 months of 1927 (168 cases) than during any of the preceding 15 years.

Cholera.—No case of cholera was reported in ports west of Bombay during the five weeks ended December 3. The last case occurred at Basrah on October 15, and Lingah was declared free from cholera on November 26. The total number of cholera cases reported in Iraq showed no decrease in the first half of November (281 cases were reported during the 4 weeks ended November 19, as compared with 270 during the preceding 4 weeks) although the epidemic was under complete control in the original centers of infection. A comparison of the incidence in the present epidemic with that in the previous epidemic of 1923 is given in Table 1.

Table 1.—*Cholera cases and deaths reported in Iraq, by Provinces, during the epidemics of 1923 and 1927*

Province	July 17 to Nov. 11, 1927		Aug 11 to Nov. 23, 1923

A fresh outbreak of cholera in Bengal caused the total incidence in India to increase in October in spite of a substantial decrease in the Deccan as well as in the Upper and Middle Ganges Plain. Deaths from cholera in the various Provinces of India in recent months are shown in Table 2.

Table 2.—*Deaths from cholera in the Provinces of India, by fortnightly periods, from July 3 to October 22, 1927*

[1] One week only.

Cholera continued to decrease in French Indo-China. During the first 20 days of November 105 cases were reported in Cambodia, Cochin-China, and southern Laos, 88 in Annam, and none in Tonkin. In Siam there were 53 cases in the four weeks ended November 5.

The Philippine Islands were practically free from cholera during 1927.

Yellow fever.—The incidence of yellow fever in Senegal decreased markedly in the second half of November. Sixteen cases were reported during the four weeks ended November 29, of which 7 were at Dakar, 3 at Thies, 2 each at Mekke and Sebikotane, and 1 each at Louga and Khombole. Six of these cases were among Europeans.

One case was reported on November 21 at Grand Popo in Dahomey.

Only one case was reported in October in the Gold Coast Colony, at Koforidua.

Smallpox.—The following reports of smallpox were recorded from continental European countries in October:

Seven cases in France, 4 cases in Greece, and 2 cases in Latvia. Reports for October have not as yet been received from Italy, Spain, and the U. S. S. R. In Italy there were 2 cases during the four weeks ended September 25. Four cases were reported in the Ukraine in August.

The incidence of mild smallpox in England and Wales increased in November but was not higher than at the corresponding season of last year. During the four weeks ended December 3 there were 1,083 cases, as compared with 1,200 during the corresponding four weeks of 1926.

In Algeria the severe type of smallpox has been prevalent during 1927. In October and November its incidence increased; 683 cases were reported in October, and 661 cases in the three weeks ended November 19. The epidemic is most extensive in the department of Oran. In Tunis 45 cases of smallpox were reported during the four weeks ended November 27.

An outbreak of severe smallpox in Northern Rhodesia is indicated by the report for October. In the five weeks ended November 4, 317 cases and 75 deaths were reported, as compared with 183 cases and 22 deaths in the third quarter of last year.

Enteric fever.—The seasonal maximum incidence of enteric fever was later than usual in most European countries, and nearly everywhere the disease was more prevalent than in 1926. Only in Germany, the Netherlands, and Sweden was the incidence in 1927 considerably lower than in 1926. The disease has been much more prevalent than in the preceding year in Poland, Rumania, the Kingdom of the Serbs, Croats and Slovenes, Bulgaria, Greece, and Italy. The incidence in European countries in the past year is compared with that in the preceding year in Table 3.

Influenza.—No unusual prevalence of influenza had been reported by any European country up to the middle of December.

Lethargic encephalitis.—A decrease in cases of lethargic encephalitis in 1927 is noted in the reports of the few countries in which this disease is notifiable. In England and Wales, 1,483 cases had been notified up to December 3, 1927, as compared with 2,120 cases in 1926, 2,483 cases in 1925, and 4,825 cases in 1924.

Acute poliomyelitis.—The epidemic of poliomyelitis in Germany decreased rapidly in the second half of October and in November. The center of the epidemic was the Province of Leipzig.

In Denmark, fewer cases of poliomyelitis were reported in 1927 than for several years past, and the incidence in Sweden, though higher than in 1926, was lower than in 1924 or 1925.

DEATHS FROM AUTOMOBILE ACCIDENTS IN 76 LARGE CITIES OF THE UNITED STATES, 1926 AND 1927

The Department of Commerce announces that for the 52-week periods ended December 31, 1927, and January 1, 1927, the total numbers of deaths resulting from automobile accidents in 76 large cities of the United States were, respectively 7,016 and 6,586, indicating a death rate for this cause of 22 per 100,000 population in 1927

as compared with a rate of 21 in 1926—an increase of 5 per cent in the rate last year. The following table gives the number of deaths from such accidents and the death rates per 100,000 population for these cities for each of the two years:

Number of deaths from automobile accidents and death rates for 76 large cities of the United States, 1926 and 1927

(From the Bureau of the Census, Department of Commerce)

DEATHS FROM AUTOMOBILE ACCIDENTS BY FOUR-WEEK PERIODS, APRIL 26, 1925, TO DECEMBER 31, 1927

The following table gives the total number of deaths from automobile accidents in 76 large cities, by four-week periods, from April 26, 1925, to December 31, 1927. The lowest number of deaths from this cause for a four-week period during this time was 345, for the period ended March 27, 1926, and the highest was 681, for the four weeks ended November 5, 1927.

Total number of deaths from automobile accidents in 76 large cities of the United States, by four-week periods, April 26, 1925, to December 31, 1927

Four weeks ended—

COURT DECISIONS RELATING TO PUBLIC HEALTH

Milk ordinance held valid.—(Oregon Supreme Court; Korth *v.* City of Portland et al.; Georgeson *v.* Same, 261 P. 895; decided November 29, 1927.) Suits were brought against the city of Portland by which it was sought to restrain the enforcement of an ordinance relating to milk sold within the city. The ordinance prescribed various requirements relative to the production and handling of milk, all of which were designed to secure the purity of same, and also imposed a license fee. The plaintiffs produced milk on dairy farms outside of the city, but sold the milk within the city. One of the contentions against the ordinance was that it was an attempt to exercise extraterritorial power. But the supreme court held adversely to this view, as the requirements touched only those persons who sold milk within the city. Another contention was that a State law, which related to peddlers, prevented the city from levying a license fee, the law providing that "Nothing contained in this act shall be deemed to impair or restrain the right of any incorporated city or town to enact and enforce reasonable regulations without imposing licensing fees, to require purity and wholesomeness in milk and other foods." However, the supreme court held that the quoted sentence was a nullity because not germane to the title of the act and thus in contravention of the State constitution. Regarding the license fee prescribed by the ordinance, the court stated:

> Such license fee is not levied for peddling. It is not provided for revenue primarily. It is a reasonable provision for the proper inspection and regulation of the sale of milk within the city Those who are selling milk are required to register and pay a license, not because they are selling as peddlers, but to insure the proper regulation for the protection of the inhabitants of the city.

A third contention, against which the court also decided, was that the ordinance was void because it conferred arbitrary and unregulated power upon the health officer. In concluding its opinion, the court said:

> It follows that the ordinance attacked * * * is a valid exercise of the police power of the city of Portland Plaintiffs have not complied with the valid provisions contained in the ordinance. The decision sustaining the demurrer and dismissing the bill is correct, and the decree of the circuit court is therefore affirmed.

Operation of swimming pool enjoined to prevent pollution of city water supply.—(Texas Court of Civil Appeals; Newton et al. *v.* City of Groesbeck, 299 S. W. 518; decided October 6, 1927.) For the purpose of preserving the purity of its water supply, a city brought suit to enjoin the operation of a commercial swimming pool and bathhouse, which was so located that its use would have contaminated the city supply. There was a statutory provision to the effect that no one had a right to pollute any water course or other public body

of water which was being used for drinking and domestic purposes. The trial court granted an injunction restraining the operation of the swimming pool and bathhouse, and on appeal the judgment of said court was affirmed by the court of civil appeals.

Recovery denied licensed scavenger for cleaning of privy vaults.—(Minnesota Supreme Court; Meinke *v.* Jannette, 216 N. W. 534; decided November 25, 1927.) The plaintiff, a licensed scavenger, brought an action to recover a certain amount for cleaning several privy vaults owned by defendant. The plaintiff had no agreement with the defendant for said cleaning, and the defendant did not consent to the doing of the work. Also no notice in writing to clean the vaults had been given to the defendant by the city health department as provided by city ordinance. The supreme court, in deciding against the plaintiff, held that the said written notice was essential.

PUBLIC HEALTH ENGINEERING ABSTRACTS

The Milk and Dairies Order, 1926. F. A. Belam. *Public Health* (British), vol. 4, No. 12, September, 1927, pp. 395–397. (Abstract by H. V. Pedersen.)

This article is a critical discussion of the 1926 milk and dairies order of England. Doctor Belam points out the good features of the order and also calls attention to a number of clauses, the meaning of which is not clear. The author openly challenges the probability of enforcing the order as it relates to proper washing of udders, flanks, etc., and preventing the use of milkers suffering from infectious diseases.

The author closes his discussion by outlining four definite recommendations for the purpose of arousing further discussion and which might also be useful to the Ministry of Health in amending the order. Although it is difficult for a reader unfamiliar with the order to follow the discussion, the four recommendations are quoted as follows:

1. It should be specified clearly to what sanitary requirements the 18 months' notice applies, and made clear that this notice is needed only when requirements justify it.

2. The particulars of registration should be clarified as to who must register, etc., and should define dairy to include milk shops; also dairyman should be defined. All farmers producing milk for sale should be registered, and no loophole of escape should be given.

Local authorities should be empowered to refuse registration for unsuitable premises, and if refused, sale of milk should be prohibited until registration is granted.

3. Model regulations specifying in detail as to air space, lighting and ventilation, drainage channels, flooring (impervious), walls (impervious covering), etc., should be immediately drafted so that farmers in all areas would have exactly the same requirements to carry out. It should be clearly stated that inlet and outlet ventilators to the open air are needed, and clear definitions of all sanitary desiderata should be included. This would remove the justifiable complaint of different standards in different areas, and would materially assist enforcement of regulations in courts of law by eliminating phrases such as "adequate lighting" or "suitably ventilated," which have no real meaning at all.

Included in these should also be insistence on removal of manure before each milking; the hanging up of milking stools and the cooling of all milk at the farm should be demanded. The provision of a dairy should also be insisted upon.

4. In the case of farms not owned by the farmer, both tenant and landlord should be served with any notice. At present it is legal only to call upon the tenant farmer to carry out alterations, which is very hard upon those with yearly leases, or whose landlord invariably refuses to cooperate. Dual service of notice would make the landlord also liable in law, and then an agreement between him and his tenant farmer could be arrived at.

Pasteurization of Milk for Small Communities. B. Evan Parry. Publication No. 36, Department of Health, Canada, 1926. 83 pages. (Abstract by P. R. Carter)

This publication gives a more or less detailed discussion of raw and Pasteurized milk in their relation to the public health.

The various phases of the production and handling of raw milk are given. These include a discussion of the more common defects and methods of overcoming them and certain illustrations. Plans of dairy barns are appended.

The article describes the steps taken in the Pasteurization of milk. Various types of equipment, such as clarifiers, Pasteurizers, coolers, pumps, bottle fillers and cappers, and bottle washers are described and illustrated. Typical Pasteurization plant arrangements are also illustrated. A copy of the United States Public Health Service standard milk ordinance is appended

In conclusion the article states: "The relation between an unclean and infected milk supply and infant mortality is becoming more and more obvious. The decline in the so-called infectious diarrheas of infancy in our large cities, coinciding with more universal Pasteurization of milk, is clinical evidence in favor of this relationship. The residual incidence of these diseases may be ascribed to imperfect Pasteurization, improper care of milk before and after Pasteurization, and perhaps more especially to ignorance and carelessness of those who have to do with the handling of the milk in the home. No matter how carefully the production and transportation of milk may have been supervised; no matter how wholesome it may have been when left on the doorstep, the use of dirty hands and unclean utensils and failure to keep properly cooled may allow a lethal infection to enter between that stage and the infant's stomach."

Use of Hypochlorites as a Sterilizing Agent for Dairy Utensils. W. A. Hoy and Janet R. L. Rennie. *Journal of Hygiene* (British), vol. 26, No. 2, July, 1927, pp. 127–131. (Abstract by P. R. Carter)

Since disinfectants containing hypochlorites have been used for the sterilization of dairy utensils, and it has been claimed that such disinfectants are more effective than steam sterilization, this question was studied in the interests of the milk industry. Three proprietary disinfectants were studied. These contained "available chlorine" as follows: A—1.22 per cent; B—1.06 per cent; C—0.49 per cent.

Four series of experiments were conducted on milk churns of 10 and 17 gallons capacity, and the influence of different methods of treatment of the churns on the keeping qualities of milk and on the bacteriological condition of the churns was studied. The technique used in performing the experiments is given and the results are tabulated in the form of protocols.

The authors give their conclusions as follows: (1) The amount of "available chlorine" contained in these disinfectants varied from 1.23 per cent in disinfectant A to 0.49 per cent in disinfectant C; (2) a 6 per cent solution of disinfectant A failed to give the same degree of sterility in a churn as can be obtained by steam under working conditions; (3) the use of a chlorine preparation as a means of sterilizing churns necessitates the subsequent washing out of the churns with

water if the chlorine is to be removed before milk is added. This process introduces the danger of recontamination of the churn; (4) if the churn be not washed out after treatment with a chlorine preparation, there is grave danger that chlorine will be added to the milk. That this danger is not altogether hypothetical would appear to be the case, since in the United States where this method of sterilization is more extensively used than in this country, the Department of Agriculture has issued a bulletin describing a method for the detection of hypochlorites and chloramines in milk and cream. (U. S. Department of Agriculture Bulletin No. 1114, August, 1922.)

Mobile Milk Laboratory. Paul F. Krueger. *Illinois Health News*, vol. 13, No. 9, September, 1927, pp. 287-291. (Abstract by H. D. Cashmore.)

The Illinois Pasteurization law of 1925 made provisions for a mobile milk laboratory. After careful investigation and study as to its type, a very efficient laboratory was built which is now available for use in that State.

Visits will be made to the 352 plants located in 153 towns, and tests made of the quality of raw milk received, efficiency of the Pasteurization plant, and quality of milk distributed to consumers. The tests will include temperature, acidity, sediment, and bacterial content of milk at the different stages of the process, and, in addition, tests of the cleansing solutions and wash water. The field personnel consists of three men.

The laboratory is carried in a 21 passenger truck of the street-car type. A central aisle of full length, a 12 foot and a 9-foot bench with ample cabinet and drawer space, and a white enamel sink are built in. Water is furnished from a 24-gallon underslung pressure tank, electricity from a dual wiring system, and gas from presto-lite tanks. The sterilizers are heated by gasoline stoves, and the incubator and milk grader by electricity or gas.

It is possible for two cots to be placed in the aisle for sleeping in case of necessity, and heat is obtained from two exhaust heaters or 110-volt electric heaters.

Viability of Pathogenic Organisms in Butter. A. E. Berry. *Journal of Preventive Medicine*, vol. 1, No. 6, July, 1927, pp. 429 442. (Abstract by C. T. Butterfield.)

The author has determined the longevity of a number of pathogens in butter. The organisms and the numbers of days each was found to survive, follow: *A. aertrycke*, 273 days; *B. schottmulleri*, 293 days; *B. enteritidis*, 272 days; *B. typhosus* (Mississippi), 56 days; *B. typhosus* (Talladega), 292 days; *B. paratyphosus* A, 104 days; *B. suipestifer*, 73 days; *B. dysenteriae* (Flexner), 84 days; and *Streptococcus scarlatina*, 41 days. At no time was an increase observed.

The less resistant organisms decreased rapidly at the start; others showed a more gradual decline in numbers. The temperature of storage did not seem to affect markedly the rate until the butter became rancid; this destroyed all organisms rapidly.

The author also gives results with water and milk, reviews the literature of the subject, and gives a detailed description of his methods, procedure, and results.

On a basis of these results, butter must be considered a potential factor in the spread of communicable diseases.

Food Poisoning. Anon. *The Lancet* (No. 17 of vol. 2, 1927), No. 5434, vol. 213, October 22, 1927, p. 900. (Abstract by W. L. Havens.)

This article contains excerpts from a lecture delivered at the B. M. A. House, Tavistock Square, when Dr. W. G. Savage dealt with the subject of food poisoning.

On account of the necessity for conserving food supplies for long periods of time and the public demand for foods prepared in different ways, the problem of food poisoning has become an important item of public health work. Food

poisoning may be traceable to many different sources. Illness may be caused by a definitely poisoned plant or animal being consumed, as in the case of mushroom poisoning. Other sources include chemical poisoning from substances accidentally introduced into foods and bacteria developing in diseased meats and decomposed foods. These bacteria are frequently found in man-handled foods and even in foods which have been heated; they may be introduced accidentally during the subsequent cooling process.

Among the methods mentioned for preventing food poisoning may be included: (1) More rigid meat inspection; (2) sterilization of foods; (3) prevention of dust infection; (4) promotion of general cleanliness wherever foods are prepared or handled; (5) rat and mice extermination; (6) registration of all premises preparing and manufacturing made-up foods.

Another Milk-Borne Typhoid Epidemic. George D. Heath. *Illinois Health News*, vol. 13, No. 9, September, 1927, p. 281–284. (Abstract by H. D. Cashmore.)

A dairyman at Ullin had some sickness in his family prior to July 1, none of which could be definitely diagnosed as typhoid. However, the family of a neighbor did the work at the dairy and handled all the milk. There was sickness in this family prior to or about June 1, which was definitely proved to be typhoid fever and not malaria as had at first been thought. Evidently the neighbor's wife was an active carrier and handled the milk.

As a result of this condition there were found 8 cases of typhoid fever in Cairo, 5 in Mounds, and 1 case in Ullin among people who were known to use the raw milk from above-mentioned dairy which was being delivered to these towns. No new cases were reported after stopping the sale of milk from this dairy.

This situation indicates that there was some carelessness in regard to the handling of the milk from the dairy; and such cases point out the necessity for a law regulating the examination of food handlers.

Use of a Differential Stain in the Direct Enumeration of Bacteria in Pasteurized Milk. Margaret Beattie. *American Journal of Public Health*, vol. 17 No. 10, October, 1927, pp. 1031–1034. (Abstract by C. T. Butterfield.)

The literature dealing with the direct counting of bacteria in milk is briefly reviewed. A method of making direct counts of bacteria is given which differentiates between the living and the dead bacteria as well as gives the total count of both groups. A modification of Proca's methylene blue-fuchsin stain is employed.

The author concludes that in a comparison of plate counts of 31 samples of Pasteurized milk with direct counts, the latter vary less among themselves. There is a positive correlation between the two methods.

Raw Water Chlorination Experiments at Sandusky. O. F. Schoepfle. Sixth Annual Report of Ohio Conference on Water Purification, October, 1926, pp. 9–10. (Abstract by F. H. Waring.)

The increasing pollution of the raw water supply of Sandusky has taxed the purification plant to such extent that it has been impossible to produce an effluent, before chlorination, which is within the Treasury Department Standard.

The Sandusky water purification plant was reconstructed in 1914. It consists of 2 coagulating basins, 10 filters of 1 m. g. d. each, 2 clear wells, and equipment for coagulation of the water with a solution of aluminum sulphate and disinfection with liquid chlorine. The raw water intakes are two in number located in Sandusky Bay within 2,000 feet from shore.

Experiments were begun May, 1926, with prechlorination of the raw water to reduce the bacterial load on the water purification plant. A direct feed chlorinator was set up in an intake well in the raw water supply line about

500 feet ahead of the point of application of coagulant. Chlorine was applied at rates varying from 0.68 p. p. m. to 0.36 p. p. m., so that a residual chlorine of 0. 02 p. p. m. was present at the raw water suction well after a reaction period of about 10 minutes. Residual chlorine was entirely absent from the water when it reached the filters.

The number of bacteria in the raw water was reduced 70 per cent, and the number of *B. coli* was reduced 80 per cent before application of coagulant. Aside from its effect in bacteria removal, an improvement was noted in coagulation which permitted a saving of 20 per cent in coagulant. Also less trouble was experienced with algae. No satisfactory explanation for the improvement in the coagulation of prechlorinated water was arrived at.

In conclusion, it is stated that prechlorination of the raw water at Sandusky not only makes it possible to produce a filter effluent within the Treasury Department Standard, but effects a considerable saving in coagulant.

In general, the writer concludes that raw water chlorination can be advantageously employed in all water plants treating a highly polluted water where the products of chlorination are not offensive to taste and smell.

Description and Operating Results of the Girard Water-Softening Plant. Brooks D. Church. Sixth Annual Report of Ohio Conference on Water Purification, October, 1926, pp. 11–12. (Abstract by F. H. Waring.)

Girard is situated in Trumbull County north of the city of Youngstown. The water works was purchased by the city in 1922, and in 1925 a modern water-softening plant was constructed. The supply is obtained from an abandoned coal mine at a depth of 160 feet. The water is hard and has a high iron content. Consumption is about 400,000 g. p. d.

The softening plant consists of mechanical mixing chambers, settling basins, recarbonation chambers, two filters of one-half m. g. d. capacity each, a clear well of 93,000 gallons capacity, and two elevated storage tanks of 512,000 gallons total capacity. Chemical equipment consists in dry feed machines for application of lime and a carbon dioxide generating plant. The mixing chambers are four in number, 7 feet square in plan, and 14 feet deep. The retention period is 30 minutes. The tanks are provided with horizontal paddles which are rotated at the rate of 3 r. p. m. The settling basins have a retention period of three and one-half hours, and the outlet of each is over a skimming wall into the recarbonation chambers. These are 9 feet 3 inches by 10 feet 9 inches in plan and 12 feet 6 inches deep above the distribution grids. The grids in each chamber are perforated with 64⅛-inch openings spaced 14 inches one way and 16 inches the other way.

The carbon dioxide gas plant consists of a crusher for coal, a magnetic separator to remove foreign particles of iron, a feeder to the pulverizer, a combined pulveriser and blower which delivers coal to the furnace where it is turned to complete products of combustion. A scrubber and drier are provided and a motor-driven centrifugal water piston pump discharging into a receiver which is connected to the distributing grids. This plant will produce 21 pounds of CO_2 per hour.

Floats are provided in the clear well which actuate automatic starts and stops on the low service pumps. High service pumps are also automatically controlled by automatic devices actuated by a pressure regulator.

The quality of the supply is such that no disinfection is required. Bacterial analyses are made daily by the chemist in charge. Chemical analyses indicate

that by the application of 10 g. p. g. of lime (as CaO) the hardness is reduced from 192 p. p. m. to 90 p. p. m. Recarbonation removes all the carbonates and an excess of about 2 p. p. m. of CO_2 is present in the filtered water.

Combination of Excess Lime, Double Coagulation, and Adjustment of pH Value at Ironton. E. T. Edwards. Sixth Annual Report of Ohio Conference on Water Purification, October, 1926, p. 9. (Abstract by F. H. Waring.)

On account of the high bacterial content of the water in Ohio River from which the Ironton public water supply is obtained, double coagulation followed by filtration and disinfection has been practiced for several years. Prechlorination of the raw water was tried in 1925, but was discontinued on account of the disagreeable tastes produced, due to the presence of phenols in the water.

Excess lime treatment of the raw water was therefore tried in an effort to render the water safe without having to depend on chlorine disinfection. Lime was applied at the rate of 2 to 3 g. p. g. in the primary settling basin. A causticity of about 5 p. p. m. was obtained. Treatment was later increased to produce a causticity of about 20 p. p. m. Alum was applied in the mixing chamber preceding the secondary settling basin for the double purpose of removing the turbidity and lowering the pH value of the caustic water so that no incrustation of the sand would take place. The amount of alum required to produce a water free from carbonates was excessive, and experiments were conducted in the application of CO_2 to the lime-treated water. A machine called a "Ceco spray" was tried out. Its function was to absorb CO_2 from the gas given off by burning coke in the heating furnace. The results of these experiments proved that an insufficient amount of CO_2 could be absorbed by this machine and preparations are now being made to install a regular CO_2 generating plant consisting of the furnace, a scrubber, a drier, a compressor, and a distributing grid which will be located in the mixing chamber. Bacterial results have been fairly satisfactory. By excess lime treatment in the primary basin the *B. coli* index has been reduced from about 30,000 to 100 per 100 c. c. Even better results are hoped for when this method of treatment is continuous. No incrustation of the sand in the filters is taking place. The filters have become a true factor of safety and chlorine may be dispensed with at will. A saving in coagulant is effected when excess lime treatment is followed by recarbonation with CO_2 gas.

DEATHS DURING WEEK ENDED JANUARY 21, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended January 21, 1928 and corresponding week of 1927. (From the Weekly Health Index, January 25, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended Jan 21, 1928	Corresponding week 1927
Policies in force	69, 723, 381	66, 588, 121

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[5] Deaths for week ended Friday, Jan. 20, 1928.
[6] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Louisville, 17; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; and Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 100 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 31,100,000. The estimated population of the 94 cities reporting deaths is more than 30,400,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended January 14, 1928, and January 15, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
41 States	2,295	2,069	
100 cities	1,186	1,094	1,121
Measles:			
40 States	11,337	8,489	
100 cities	2,941	2,018	
Poliomyelitis:			
41 States	65	18

City reports for week ended January 14, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

81881°—28——3

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended January 14, 1928, compared with those for a like period ended January 15, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, December 11, 1927, to January 14, 1928—Annual rates per 100,000 population, compared with rates for the corresponding period of 1926-27 [1]

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended December 31, 1927.—The following report for the week ended December 31, 1927, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt—Alexandria
India—Bombay, Rangoon, Bassein
Dutch East Indies.—Makassar

CHOLERA

India—Negapatam, Calcutta, Rangoon
Straits Settlements—Singapore
Siam—Bangkok

SMALLPOX

Aden—Aden
Iraq—Basra
India—Bombay, Calcutta, Rangoon
French India—Pondicherry
Dutch East Indies—Belawan Deli, Surabaya.
Siam—Bangkok
French Indo China—Saigon

Returns for the week ended December 31 were not received from Madras, India, Colombo, Ceylon, Canton, China, Samarinda, Dutch East Indies, or Vladivostok, Union of Socialist Soviet Republics.

ARABIA

Aden—Epidemic plague—January 23, 1928.—Under date of January 23, 1928, plague was reported present in epidemic form at Aden, Arabia.

ARGENTINA

Rosario—Plague—Measures against spread.—Press reports from Buenos Aires, Argentina, state the recent occurrence of six cases of plague at Rosario. Notices from the same source show that active measures against the spread of the disease are in force at Rosario, including campaign against rats, which are stated to exist in great numbers in the port, and the immunization of about 300 workmen.

BELGIAN CONGO

Matadi—Yellow fever.—Further information relative to yellow fever at Matadi, Belgian Kongo, reported present January 3, 1928,[1] shows under date of December 25, 1927, 9 suspect cases, 6 fatalities from the disease, and 2 cases under observation.

[1] Public Health Reports, Jan. 27, 1928, p. 240.

BRAZIL

State of Parahyba—Health conditions—July, 1926, to June, 1927.—Information received under recent date shows the sanitary and general health status of the State of Parahyba, Brazil, during the year, to have been satisfactory, with exception of increased mortality from malarial diseases, tuberculosis, and gastroenteritis in children.

Influenza.—Some cases of influenza were reported at Alagoa Nova and Teixeira. At Cajazeiras and Misericordia smallpox made its appearance. Medical relief was supplied to these localities by the Department of Health.

Plague.—An outbreak of plague occurred during the period under report at the town of Sape, with 42 cases and 36 fatalities. The infection was attributed to rats which were brought into the town in a consignment of packing cases, containing, it was stated, machinery for installation in a large sugar plant.

Rural sanitation.—Rural sanitation was stated to be in progress, being directed mainly to the eradication of hookworm disease, leprosy, malaria, and the venereal diseases, the work being carried on at 23 stations throughout the State and in the capital city.

Water works and sewer construction.—The water works and sewerage system were declared completed as regards the capital city, Parahyba, January 24, 1926, but the work of house connections and extension of water lines was not finished. The water supply system of Campina Grande was officially opened in October, 1927.

Yellow fever prevention work.—The work of yellow fever prevention was stated to have been carried on during the year. The last case to occur in the city of Parahyba was reported in June, 1926, and the last case in the State as a whole, in August, 1926.

CANADA

Communicable diseases—Week ended January 7, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended January 7, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever			1	1				2
Influenza	14			2				16
Lethargic encephalitis				3				3
Poliomyelitis				1			1	2
Smallpox				83	2	15	3	103
Typhoid fever	7	15	22	17			1	62

Communicable diseases—Week ended January 14, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended January 14, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever			1			2		3
Influenza	7			1				8
Poliomyelitis				1				1
Smallpox	1			76	5	12	5	99
Typhoid fever	8	4	37	9		3		61

Ottawa—Mortality—Year ended October 31, 1927.—The general death rate of the city of Ottawa, Province of Ontario, Canada, for the year ended October 31, 1927, was lower than for any year previously reported, with the exception of the year 1925. The lowered death rate was attributed to lower infant mortality, viz, 74 fewer deaths of infants than for the preceding year. The total number of deaths reported was 1,551, as compared with 1,639 in 1926.

Measles—Typhoid fever—Tuberculosis.—An outbreak of measles was reported for the months of December, 1926, and January and February, 1927, the type of the disease being generally mild. There were reported 1,541 cases with 4 deaths.

The prevalence of typhoid fever was attributed mainly to the development of cases of the disease in the Gatineau district of Quebec, in which many citizens of Ottawa were employed in construction work and from which many cases were sent to Ottawa hospitals. In the city of Ottawa 28 cases originated.

There were reported 94 deaths from tuberculosis, as compared with 85 in 1926. Of this number, 82 per cent were said to be due to pulmonary tuberculosis.

Quebec Province—Communicable diseases—Week ended January 14, 1928.—The Bureau of Health of the Province of Quebec reports cases of communicable diseases for the week ended January 14, 1928, as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	1	Scarlet fever	122
Chicken pox	39	Smallpox	17
Diphtheria	98	Tuberculosis	69
German measles	2	Typhoid fever	15
Measles	137	Whooping cough	28

EGYPT

Alexandria—Plague—December 17-23, 1927.—During the week ended December 23, 1927, a case of plague was reported at Alexandria, Egypt.

Summary and comparison with corresponding period of the preceding year.—During the period January 1 to December 23, 1927, 77 cases of plague were reported in Egypt, as compared with 150 cases reported for the corresponding period of the year 1926.

ESTONIA

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported in the Republic of Estonia as follows:

Disease	Cases	Disease	Cases
Diphtheria	33	Tuberculosis	129
Measles	43	Typhoid fever	65
Scarlet fever	323		

Population, census, 1,107,059

IVORY COAST (WEST AFRICA)

Abidjan—Yellow fever—December 24, 1927.—Under date of January 4, 1928, a fatal case of yellow fever occurring in a European was reported at Abidjan, Ivory Coast, West Africa. The locality was stated to be under sanitary observation.

MADAGASCAR

Plague—October 16-31, 1927.—During the 16-day period ended October 31, 1927, 104 cases of plague with 97 deaths were reported in the island of Madagascar. The distribution according to Provinces was as follows: Ambositra, 2 cases; Antisirabe, 17; Itasy, 11; Moramanga, 20; Tananarive, 54. The distribution according to type of disease was as follows: Bubonic, 50 cases; pneumonic, 43; septicemic, 11. In the interior town of Tananarive the occurrence was as follows: Cases, 5; deaths, 5; bubonic, 1; pneumonic, 3; septicemic, 1.

SENEGAL

Dakar—Yellow fever—Diourbel, suspect yellow fever.—Under date of January 4, 1928, one case with one death of yellow fever was reported at Dakar, Senegal. On the same date one suspect case with fatal termination, occurring in a Syrian arriving from Dar-Mousti, was reported at Diourbel.

UNION OF SOUTH AFRICA

Cape Province—Plague—December 4-10, 1927.—During the week ended December 10, 1927, two cases of plague, one of which resulted fatally, occurring in the colored or native population, was reported in Hanover District, Cape Province, Union of South Africa.

Smallpox—Typhus fever.—During the same period outbreaks of smallpox and typhus fever were reported in the Union of South Africa as follows: Smallpox—Orange Free State, in one district. Typhus fever—Outbreaks in the Cape Province in the districts of St. George, Tsolo, and Xalanga. At Durban, Natal, one sporadic case, occurring in a native, was reported.

VIRGIN ISLANDS

Communicable diseases—December, 1927.—During the month of December, 1927, communicable diseases were reported in the Virgin Islands of the United States as follows:

Island and disease	Cases	Island and disease	Cases
St. Thomas and St. John:		St. Thomas and St. John—Continued.	
Chancroid	1	Syphilis	5
Dengue	1	Whooping cough	1
Gonorrhea	4	St. Croix:	
Sprue	1	Tetanus	1

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

Asst Surg Gen. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

PUBLIC HEALTH REPORTS

VOL. 43 FEBRUARY 10, 1928 NO. 6

PREVALENCE OF DIPHTHERIA IN THE UNITED STATES

The diphtheria case and death rates for the year 1926 were the lowest ever recorded. The death rate for diphtheria for that year in the registration area was 7.5 per hundred thousand, and the case rate in 47 States was 80 per hundred thousand. In 1927 there was a reaction. Preliminary reports from 37 States show an increase in 1927 over 1926 of 16.7 per cent, and an increase in 1927 over 1925 of 15 per cent. The figures are as follows:

Cases of diphtheria reported in 37 States for 52 weeks of the years 1925, 1926, and 1927

	Cases
1925	69, 624
1926	68, 668
1927	80, 152

These 37 States had a population in 1927 of about 90,500,000.

The greatest prevalence of diphtheria usually occurs in October, November, and December. The following table gives a comparison of the weekly telegraphic reports from 37 States for the last 20 weeks of the years 1925, 1926, and 1927:

Diphtheria cases reported by 37 States for last 20 weeks of years 1925, 1926, and 1927, by four-week periods

4 weeks ended—	1927	Corresponding weeks—	
		1926	1925
Sept. 10	3, 857	2, 905	3, 400
Oct. 8	5, 771	5, 171	5, 205
Nov. 5	8, 699	9, 929	7, 478
Dec. 5	9, 106	8, 970	7, 293
Dec. 31	7, 809	7, 055	5, 785
Total	35, 242	34, 030	29, 161

The increase in number of cases during the last 20 weeks of 1926 was more marked than it was in either of the other years.

SICKNESS AMONG PERSONS IN DIFFERENT OCCUPATIONS OF A PUBLIC UTILITY [1]

By Dean K. Brundage, *Assistant Statistician, United States Public Health Service*

In a previous report[2] the general results of a study of disabling sickness among employees of the Edison Electric Illuminating Co. of Boston in the 10 years ending December 31, 1924, were given. In the present communication the frequency of sickness during the last 3 years of this period is presented for certain occupations in the public utility. The record covers all absences for 1 full working day or longer on account of disability. Liberal sick leave is granted, especially to those who have been with the company more than 1 year, amounting practically to the payment of full wages during the entire period of incapacitation up to a maximum of 15 weeks.[3] During the period under review the company physician called at the homes of a large proportion of those who reported themselves as unable to work on account of sickness or accident. A physician's diagnosis was thus obtained for 81 per cent of the disabilities which lasted 2 days or more, and 58 per cent of the disablements for 1 day only, during the years 1922, 1923, and 1924.

"EXPOSURE" ESTIMATED

The most accurate method of obtaining the divisor for computing a sickness rate is to add the number of days during which each employee was on the pay roll during the period under study and divide the total by 365 (number of calendar days in the year). The quotient thus obtained represents the equivalent number of employees on the payroll for a full year. But on account of the large amount of clerical labor required to obtain the "exposure" data in this way, the population "at risk" was approximated by the following method:

The number of persons in each occupation as of July 15, 1923 (the approximate mid-point of the three years 1922 to 1924), was obtained from the pay-roll records of the company. The sex, age, and number of years in the employ of the company up to July 15, 1923, were also obtained for each person. The per cent of total persons in each occupation who were in different age and length-of-service groups was computed and applied to the sum of the average number in the occupation during each of the three years, the annual averages being based on the exact number in each occupation at the end of each month.

[2] A 10-Year Record of Absences from Work on Account of Sickness and Accidents. Public Health Reports, vol. 42, No. 8 (Feb. 25, 1927), pp. 529-550. (Reprint No. 1142.)

[3] The sick-leave provisions of the company are given in detail on p. 3 of the reprint mentioned in footnote 2.

The products which represent the approximate number of years of life under observation are given for two service groups and for all lengths of service, by occupations, in Table 10, and the sex and age distribution within each numerically important occupation are shown in Table 12. With these approximations of the equivalent number of persons under observation for one full year in the different sex, age,

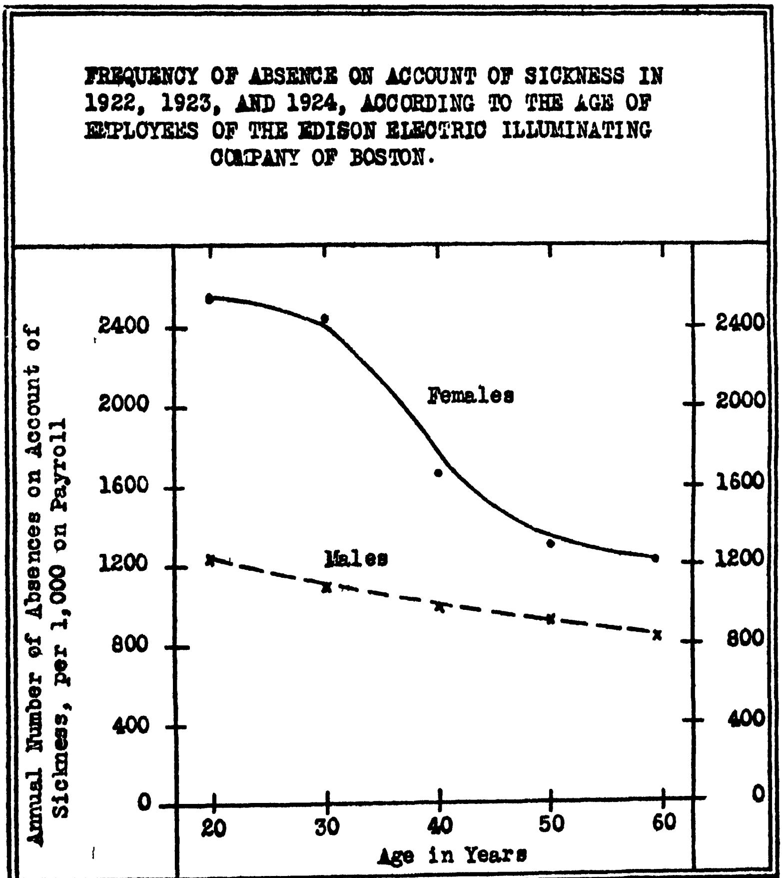

FIG 1

and length-of-service groups, by occupation, and with the absences on account of sickness similarly classified and tabulated, it was possible to express the sickness in terms of rates per 100 or per 1,000 persons in the different occupations, and according to age, sex, and length of service. The rates shown in all the tables with the exception of the last one (Table 13) do not include accidents either of industrial or nonindustrial origin.

FREQUENCY OF SICKNESS ACCORDING TO AGE

The frequency of absence for one day or longer on account of sickness gradually decreased as age advanced among the male employees of the public utility, and declined sharply between the ages of 30 and 50 among the women. This result was surprising, inasmuch as the age incidence of illness in the general population of Hagers-

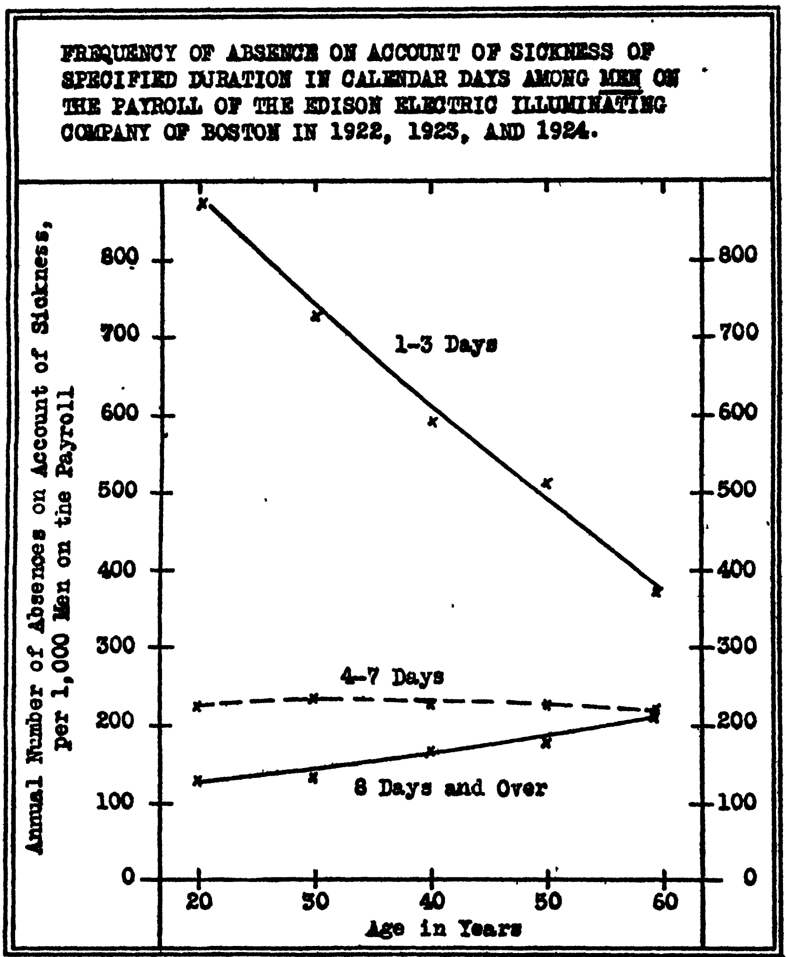

FIG. 2

town, Md., gradually increased from age 20 or thereabouts throughout the remainder of life.[4] It appears, however, that the shape of the age curve of illness depends largely upon the extent to which the more minor sicknesses are included. In early adult life the

[4] The Age Curve of Illness, Hagerstown Morbidity Studies No. IV, Public Health Reports, vol. 42, No. 23 (June 10, 1927), pp. 1565-1576. (Reprint No. 1163.)

frequency of minor illnesses, especially those which disable for a period varying from one to three days, evidently is high, if the experience of male employees of the Edison Co. is typical. In the Hagerstown study it was found by actual check that many minor cases, the one and two day disabilities especially, were not reported for school children,[5] and therefore probably were not generally reported among the adults. The recorded morbidity experience of males in the employ of the Edison Co. showed a practically stationary rate of absence throughout the working period of life from illness lasting four to seven days. The eight-day or longer disabilities, however, increased in frequency from age 20 onward.

[1] Exclusive of accidents of both industrial and nonindustrial origin.

LENGTH OF SERVICE WITH THE COMPANY

Among either sex the frequency of absence from work for 1 day or longer on account of sickness tended to decrease with increase in length of service. Among males in the employ of the company less than 5 years the incidence rate of illness was 56 per cent greater than among those with a service record of 10 years or more. Among

[5] Incidence of Sickness Among White School Children in Hagerstown, Md. Public Health Reports, vol. 40, No. 9 (Feb. 27, 1925), p. 405. (Reprint No. 993, p. 5.)

the women the difference was even wider, those employed by the company less than 5 years being absent on account of illness 72 per cent oftener than the women of 10 or more years' service.

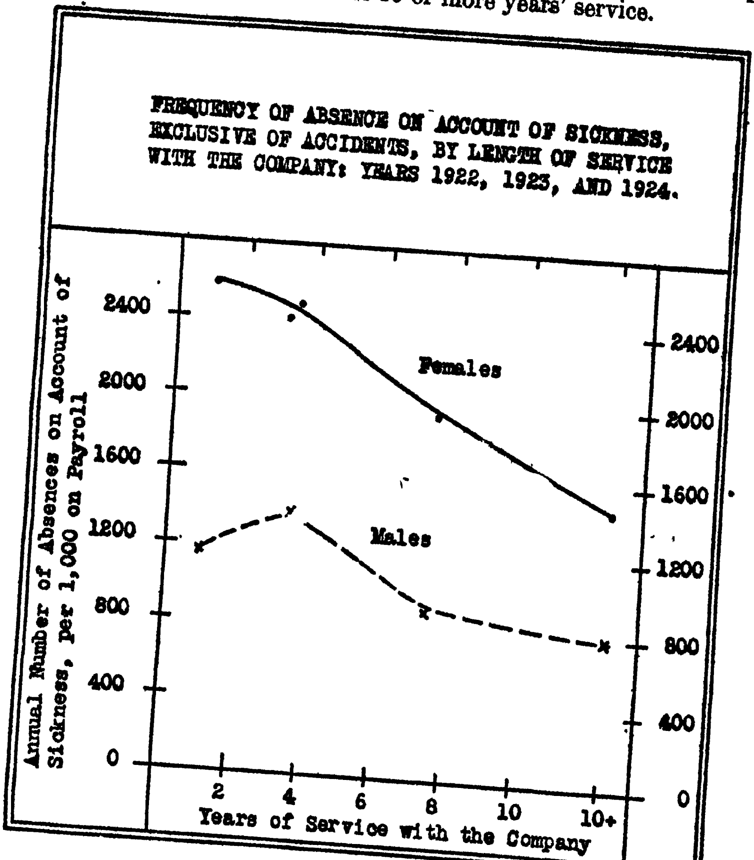

FIG. 3

TABLE 2.—*Frequency of absence on account of sickness, exclusive of accidents, among employees of the Edison Electric Illuminating Co. of Boston during the 3 years ending December 31, 1924: By length of service with the company*

Length of service	Males			Females		
	Number of years of life under observation	Number of absences due to sickness	Rate per 1,000 on the pay roll	Number of years of life under observation	Number of absences due to sickness	Rate per 1,000 on the pay roll
All lengths of service	6,120	6,399	1,044	1,508	3,475	2,304
Less than 2 years	1,928	2,225	1,154	556	1,430	2,572
2 to 5 years	1,183	1,637	1,384	485	1,207	2,489
5 to 10 years	1,469	1,303	887	331	638	1,927
10 years or more	1,549	1,234	797	136	200	1,471

Inasmuch as the trend in the frequency of disabling illness was found to be downward with increase both in age and in length of service, the question arose whether the rates according to length of service merely reflected the influence of age, since the employees of longer service would tend to be in the higher age groups. The frequency of one- to three-day, four- to seven-day, and eight-day or longer disabilities in two service groups (less than five years compared with five or more years' service) was computed, therefore, according to age. The age curves of illness among male employees of five or more years' service did not differ materially from the curves for men of less than five years' service except that disability occurred oftener at every age among the newer recruits than among the veteran employees. The contrast was especially marked in the shorter disabilities; i. e., those lasting less than eight days. Among the women the same results were indicated, although not so clearly, probably because there were only one-fourth as many women as men under observation. It may be said, therefore, that the incidence rates of illness tended to be lower in every age group among employees of five or more years' service than among those who had been with the company less than five years.[6]

TABLE 3.—*Number of years of life covered in the record, classified according to age and by length of service, among men on the pay roll of the Edison Electric Illuminating Co., of Boston, in the three years ending December 31, 1924*

Age group	All periods of service	Less than 5 years in employ of company	5 or more years' service with company
All ages	6,129	3,111	3,018
Under 25	1,310	1,218	92
25-34	1,951	1,139	812
35-44	1,543	455	1,0
45-54	908	249	659
55 and over	417	50	367

[6] Decrease in sickness frequency with increase in length of service is also revealed in other industrial morbidity data collected by the Public Health Service, but not yet published, and in "Disabling Sickness Among Employees of a Rubber Manufacturing Establishment in 1918, 1919, and 1920." Public Health Reports, vol. 37, No. 50 (Dec. 15, 1922). p. 3089. (Reprint No. 804, p. 9.)

INCIDENCE RATES OF ILLNESS IN DIFFERENT OCCUPATIONS

In Table 7 the annual number of absences due to sickness per 1,000 persons under observation is shown according to occupation. The frequency of one- to three-day, four- to seven-day, and eight-day or longer illnesses is also given to indicate the comparative severity of sickness among persons in different lines of work. The occupations have been arrayed in accordance with the magnitude of the sickness incidence rate (regardless of the duration of disability) for each occupation.

In the interpretation of these rates several points should be borne in mind. Although the chief interest of statistics of this sort lies in

their instructiveness with regard to the effect upon health of different kinds of work and working conditions, the existence of an occupational health hazard is not necessarily indicated by a high rate of illness. The rate merely states the frequency of sickness among persons following a given occupation. The more arduous occupations are of necessity recruited from men of supernormal physical condition. Persons physically unfit for the more exacting occupations and those especially susceptible to certain diseases naturally seek the light, sedentary jobs.[7] However, when the work is not of such a nature as to attract physically inferior individuals in the industrial population, and when the sex and age distribution of the groups under study do not account for the amount of illness experienced, a high sickness rate *may* indicate a causal relation between the occupation and the abnormal number of disabilities.

A factor which probably affects the incidence rate to some extent, especially the frequency of the one- to three-day absences, is the nature of the duties in the different occupations. A telephone operator, for example, is virtually compelled to lay off when suffering from almost any type of minor respiratory illness on account of its effect upon the voice and ears; but under ordinary circumstances such minor pathological conditions would not seriously interfere with the duties of the station operators, for example. This may at least partly explain why the rate of one- to three-day absences on account of sickness among the male telephone operators was 42 per cent above that of the male station operators. In general, however, the effect of these differences undoubtedly is minimized by the payment of full wages during illness, which removes the economic argument for attempting to carry on while suffering a physical indisposition.

It will be seen from Table 7 that the occupation having the worst morbidity experience among the men during the three years ending with 1924 was that of repairmen. Their illnesses of less than four days' duration occurred at an inordinate frequency, and their rate of 4 to 7 and of 8-day or longer cases was considerably higher than the average for all men in the employ of the company. About three-fourths of the men in this group are automobile repairmen on night duty in garages, engaged in repairing cars which are needed during the daytine.

Next to the highest male rate of disabling sickness was shown for the stock handlers; but on account of the small number of years of life under observation (56) the high rate for this occupation may have been due largely to chance. When the numbers are small, it

[7] This type of selection appears to be the principal explanation of the low morbidity rates among steel workers shown in "Sickness Among Industrial Employees," Public Health Reports, vol. 41, No. 4 (Jan. 22, 1926) (Reprint No. 1060), and a considerable factor in the relatively high disability rates among certain textile workers indicated from data now being collected by the Public Health Service.

is necessary to ascertain whether a high rate is sustained over a longer period.

The third from the worst morbidity rate occurred among the linemen. The frequency of eight-day or longer cases among them was not excessive, however, their high rate resulting largely from an abnormal number of disabilities of less than a week's duration. Oilmen and oilers, chauffeurs, and meter testers also appear to have experienced considerably more than the average sickness frequency among men in the employ of the company.

TABLE 7.—*Frequency of absence on account of sickness, exclusive of accidents, by occupations—Recorded morbidity experience of employees of the Edison Electric Illuminating Co. of Boston for the three years ending December 31, 1924*

[1] Duration of disability is measured in terms of the number of calendar days intervening between the date absence began and the date employee returned to work.
[2] Also their assistants and subassistants.
[3] Also typists and dictophone operators.

The frequency of the longer cases, i. e., those lasting eight days or more, was greatest among the laborers. In unskilled work, such as that of the general laborer, operation of the selective tendencies mentioned above may be especially expected. Into such work naturally drift those persons who through diminished physical or mental health find themselves unable to engage in more exacting occupations. Another group which might be overloaded with individuals below par physically are the clerks. The wide differences in sickness frequency of the male engineers, division heads, their assistants and subassistants compared with the male clerks *may* roughly measure the effect of this factor. Very interesting also is the fact that the rate of absence on account of sickness among the female clerks was 85 per cent above that of the female stenographers, typists, and dictophone operators.

DISEASE GROUPS CAUSING DISABILITY IN DIFFERENT OCCUPATIONS

In order to facilitate the study of possible occupational influences, the sickness record of persons in several of the occupations which were believed to be free from any health hazard of consequence was used as a control. Among the men the following occupations were selected for this purpose: Clerks, division heads, their assistants and subassistants, draftsmen, engineers, and salesmen; and among the women, on account of the limited selection, the record merely of the stenographers, typists, and dictophone operators. For each of the remaining occupations included in the list presented in Table 7 the number of one-day or longer absences occasioned by different disease groups is shown in Tables 8 and 9, in comparison with the number of absences from causes specified which occurred among an equal number of persons in the control group. In Table 11 the difference between the actual number of absences and the number expected from the experience of the control group was expressed in terms of the ratio of actual to expected number of absences, the ratio being 100 when the rate for the occupation was the same as in the control group.

TABLE 8.—*Number of absences on account of disease groups specified, and number expected from the sickness rates of a control group[1] among male employees of the Edison Electric Illuminating Co. of Boston in 1922, 1923, and 1924*

[1] The following occupations were included in the control group: Stenographers, typists, dictophone operators.
[2] Title numbers 11, 31, 97–107, and 109 in the International List of the Causes of Death, third revision, Paris, 1920.
[3] Title numbers 108, 110–127 in the International List.
[4] Title numbers 70–84 in the International List.
[5] Title number 141 in the International List.
[6] Title numbers 51 and 52 in the International List.

In a number of instances the differences are not significant on account of the small numbers which frequently resulted when the disabilities among persons in a given occupation were subdivided according to the nature of the illness. The numbers involved of course have to be considered.

Among the repairmen and linemen, diseases of the digestive system, respiratory diseases, and rheumatism appear to have occurred at excessive frequency. The oilmen and oilers also experienced an abnormal number of digestive and respiratory illnesses. Only six absences on account of skin diseases, however, were reported among these men during the three-year period, although furunculosis (boils) may result from handling oil. Most of the oilmen and oilers, however, are employed in power stations equipped with shower-bath facilities which are used at the close of each tour, at which time the men make a complete change of clothing. This procedure may be sufficient to prevent the development of furunculosis under the amount of exposure to oil which is incident to the duties of the occupation.

81882°—28——2

SICKNESS ACCORDING TO LENGTH OF SERVICE IN DIFFERENT OCCUPATIONS

In the occupations exhibiting high disability rates, a question of interest is whether the excess in sickness occurred among the newer employees or among those who had been with the company for a considerable period. The latter may be expected to be a more selected group, inasmuch as persons ill-suited physically to the conditions of work in a given occupation tend to quit.[8] Hence an inordinate rate of sickness among employees of five or more years' service may be of greater significance from an occupational standpoint than a high rate of illness among the new recruits.

In measuring the sickness in these two groups, the number of absences on account of illness among persons who had been engaged in the occupation specified for less than five years was compared with the number of absences expected from the average rate of sickness among men of less than five years' service in the control group, and the ratio of actual to expected number of absences was computed. Similarly, the number of disabilities according to occupation among those of five or more years' service was compared with the number expected from the rate of sickness among men in the same service group in the occupations used as a control, and the ratio of actual to expected number ascertained. The higher ratio, of course, indicated which of the two service groups within the occupation experienced the greater excess in sickness frequency.

In order to obtain the equivalent number of persons under observation for one full year (years of life) during the three-year period in these two service groups, the distribution of persons on the pay roll as of July 15, 1923, according to the number of years employed by the company, was obtained according to occupation, as previously explained, and the percentage in each service group applied to the years of life in each occupation. The pay-roll distribution and the derived number of years of life in the two service groups are shown in Table 10.

[8] This tendency is indicated in morbidity data for a group of cement workers presented in "The Health of Workers in Dusty Trades, I. Exposure to Dust and Other Conditions in a Portland Cement Plant. Public Health Bulletin No. 176, U. S. Public Health Service. In press.

[2] Stenographers, typists, and dictophone operators.

Occupations in which men of five or more years' service experienced more excessive disability rates than employees of less than five years' service, both in respiratory and in nonrespiratory diseases, were repairmen, oilmen and oilers, stock handlers, chauffeurs, laborers, and water tenders. The linemen of longer service had a considerably higher excess disablement rate from the nonrespiratory diseases than those employed less than five years, but in diseases of the respiratory system the ratio of actual to expected number of absences was about the same in either length-of-service group. The number of disabilities in excess of the expected number showed small differences according to length of service among the meter testers, janitors, and firemen.

TABLE 11.—*Number of absences on account of sickness in certain occupations among men of less than five years' service compared with five or more years in the company's service, and the number of absences expected from the sickness rates of the control group*[1]*: Years 1922, 1923, and 1924*

[1] Ratio of actual to expected number of absences. When the two coincide, ratio = 100.

Inasmuch as the frequency of illnesses of one day or longer did not show much variation according to age among the male employees of the company as a whole (*cf.* Fig. 1), it was deemed unnecessary to present the sickness rates according to occupation with the age factor eliminated. The age distribution of the personnel of certain occupations differed somewhat from that of the control group, as shown in Table 12, but it was found that in no occupation among the men did adjustment for differences in age distribution affect the rate as much as 16 per cent.

CORRELATION OF INDUSTRIAL AND NONINDUSTRIAL ACCIDENTS AMONG THE MEN

In Table 13 the frequency of industrial accidents causing disability for one day or longer is compared with the nonindustrial accident rate, by occupations, among the male employees of the company. Industrial injuries should properly be stated in terms of the number of hours of exposure (man-hours), but in the absence of wide differences in the weekly work schedule of persons in the occupations listed, the rates as shown may be sufficiently correct for comparison with the frequency of nonindustrial injuries among the same groups of workers.

TABLE 13.—*Frequency of absence on account of industrial accidents compared with nonindustrial accidents, by occupations, among male employees of the Edison Electric Illuminating Co. of Boston in 1922, 1923, and 1924*

Occupations among male employees	Number of years of life under observation	Annual rate per 1,000 men on pay roll		Number of absences	
		Industrial accidents	Nonindustrial accidents	Industrial accidents	Nonindustrial accidents

For the purpose of ascertaining whether the nonindustrial accident rate varied or did not vary in accordance with the industrial accident rate, the coefficient of correlation was computed. A coefficient of 0.432 ± 0.112 was obtained, indicative to a fairly definite extent, of the existence of a relationship between the two sets of accident rates. A cause which suggests itself as being common to both is the personal factor in accidents, to which attention has in recent years been increasingly directed.[9] This is not to say that the nature of the accident hazard in any given occupation may not still largely determine the number of injuries occurring to persons following the occupation.

ACKNOWLEDGMENTS

The Edison Electric Illuminating Co. of Boston not only made their disability records available for study, but assisted generously in the tabulation and analysis of the data. To Mr. Herbert W. Moses, superintendent employment bureau, we are especially indebted for his cooperation and advice.

[9] The question of differing individual liability to accidents under uniform conditions of risk has been treated statistically by Major Greenwood and Hilda M. Woods in Report No. 4 of the Industrial Fatigue Research Board of Great Britain, in "A Report on the Incidence of Industrial Accidents upon Individuals, with Special Reference to Multiple Accidents," and by Ethel M. Newbold in "Practical Applications of the Statistics of Repeated Events, Particularly to Industrial Accidents," in Journ. Royal Statistical Society Vol. XC, Part III, 1927, London, England.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Two Years' Operation of the Sewage Treatment Plant at Worcester Mass. R. S. Lamphear. *Journal Boston Society of Civil Engineers*, vol. 14, No. 8, October, 1927, p. 450. (Abstract by H. D. Cashmore.)

Sewage has been treated since 1890 with marked success at Worcester. Advancements in treatment of sewage and recognition of the shortcomings of the old plant resulted in the construction of a new $3,800,000 plant, which was put in service in June, 1925.

The sewage from 235,000 people is treated in addition to storm sewage which is taken in from 35 per cent of the system. The plant is designed for a daily average of 28 million gallons, or an estimated population of 242,000 in 1939. Great fluctuation in volume is due to storms, but the system has been found capable of handling any amount. A great amount of industrial wastes is also handled.

The system consists of two large grit chambers which remove 4 cubic feet of material per million gallons of sewage, two bar screens at the outlet end of the grit chambers, 12 Imhoff tanks, each having a capacity in the sedimentation chamber and sludge compartment of 1.34 and 2.54 cubic feet, respectively, 4 pairs of dosing tanks, 4 units of trickling filters comprising 13.68 acres, 4 secondary settling tanks 60 by 120 feet in size, and 23 sludge drying beds which were formerly the old intermittent sand filters of 1 acre area each.

In 1926 the total cost of treatment of sewage averaged $7.37 per million gallons. In general, the plant works very well, but certain improvements can be made in the details which will increase the efficiency to some extent.

Progress on Cooperation with Ohio Manufactures in Proper Disposal of Industrial Wastes. F. H. Waring. Sixth Annual Report of Ohio Conference on Water Purification, 1926, pp. 60–63. (Abstract by R. E. Tarbett.)

Seventy-five filtration plants serving over half of the population of the State make control of stream pollution particularly important in Ohio. A stream pollution law and a sewer rental law have furnished the necessary remedial legislation. Plans for correcting industrial waste pollution have been developed through cooperation with manufacturers taken in groups according to the character of wastes produced.

The article covers the various groups that have been organized and the progress made by each. These groups at present include the by-product coke industry, the paper manufacturers, the milk and dairy industry, the canning industry. Many of these are not confining their activities to Ohio alone.

At present Ohio, Pennsylvania, West Virginia, Kentucky, Maryland, and New York are bound together in an agreement of uniform policies relative to interstate stream conservation, and Indiana, Illinois, and Tennessee have signified their desire to join the group.

Phenol Wastes in Ohio River Watershed. E. S. Tisdale. *Water Works*, vol. 66, No. 7, July, 1927, pp. 284–285. (Abstract by Arthur P. Miller.)

This article outlines the steps taken by States on the Ohio River Basin to eliminate phenolic and other tarry substances from the river and discusses the further cooperative agreements between those States which culminated in the Board of Public Health Engineers of the Ohio River Basin.

Nauseating medicinal tastes in Cleveland's public water supply in 1922 necessitated action on the part of the Ohio health authorities. At the request of the Ohio State Department of Health the United States Public Health Service in May, 1923, called a phenol conference in Washington to take testimony and evaluate this problem from a national standpoint. One month later the by-product coke companies met with that State health department and agreed

upon a policy to keep phenolic wastes out of Ohio streams. In January, 1924, at another conference called by the United States Public Health Service, an organization of States on the Ohio River watershed was effected. Following this meeting an engineer of the Public Health Service was detailed to make a study of the extent of phenol waste pollution.

In April, 1924, a meeting was held in Pittsburgh, where several State health departments and executives of all by-product coke manufacturers met to hear and discuss the Public Health Service report and to formulate policies for the cooperating States to carry out, working with the industries. In November, 1924, the State health departments of Pennsylvania, Ohio, and West Virginia entered into an interstate stream agreement with respect to phenol waste disposal. Kentucky later became a signatory to this agreement. In April, 1927, a survey by the respective State health departments showed that phenol discharges in the rivers had been greatly reduced and that complete elimination would soon be in effect. This cooperative effort between States led to the organization of the Board of Public Health Engineers of the Ohio River Basin.

Sewage Farm Covers 13,602 Acres. Anon. *Engineering News-Record*, vol. 99, No. 17, October 27, 1927, p. 669. (Abstract by A. S. Bedell.)

An abstract of an article in *The Engineer* (London), November 12, 1926, page 519, describing the method of sewage disposal of Melbourne metropolitan area (Victoria, Australia). The land was "originally treeless, almost stoneless, open plain country, somewhat clayey and poorly grassed," having an average annual rainfall of 18.14 inches.

The farm is sown with lucerne, pasture grasses, and clover, and is flooded with sewage and used for raising hay and for grazing. Except in winter or very wet weather, the farm takes 3 inches of sewage every two or three weeks, or 5½ feet per year, 8,084 acres being under irrigation. Dairying is not permitted, but grazing and raising cattle and sheep are carried on. On June 30, 1925, there were 6,671 cattle, 4,947 sheep, and 800 horses, with 200 employees on the farm. Revenue from grazing usually is greater than cost of sewage treatment, aside from capital charges, while in years of drought the revenue meets all charges.

City Sewage Disposal Plant Held to be a Nuisance. Warren J. Scott. *Water Works*, vol. 66, No. 10, October, 1927, p. 422. (Abstract by H. B. Hommon.)

Property owners of the town of Marlin, Tex., living near the sewage disposal plant brought suit against the City of Marlin to restrain the operation and the enlargement of the city's sewage disposal plant and to require the city to move the plant to another locality. The property owners alleged that the plant caused offensive odors and gases to emanate which were detrimental to health and prevented them from occupying their residences with any comfort. The cause was submitted on special issues, and by judgment of the trial court the city was permanently restrained from maintaining its existing sewage disposal plant and enjoined from enlarging it at the place where it was then located and was also required within six months to remove the plant to another place. The trial court's judgment was affirmed by the court of civil appeals, which said: "The evidence shows beyond controversy that the present system is exceedingly offensive to all of the appellees, as well as a large number of other citizens of Marlin * * * We think the evidence is sufficient to support the jury's finding that the proposed plant which the city is preparing to erect will cause the same offensive odors and that the same objections may be urged against it * * * It seems to be the settled law of this State that a city may, the same as a private individual, be restrained from maintaining a nuisance. * * * "

A Small Sewage Works in a Nottinghamshire Colliery District. E. J. Silcock. *Surveyor*, vol. 72, No. 1855, August 12, 1927, pp. 141–143. (Abstract by C. C. Ruchhoft.)

This plant was designed to be constructed in three units, each unit to treat the sewage from a population of 5,000. The first unit has been operating for some time, the second is about to be built, and the third will be built when needed. The plant receives sewage from a partially separate system and was designed for a flow of 20 gallons per capita per day. The detritus and screening chambers are in duplicate and have ample capacity to handle the sewage from a population of 15,000, so that a third installation will not be required. The plant, with the second unit, includes 2 Dortmund type tanks, 4 circular percolating bacteria beds, 2 secondary settling tanks also of the Dortmund type, 2 storm water tanks, 20 sludge dry beds, and a pumping station. The storm water is distributed by means of submerged orifices. One of these passes three times the dry weather flow to the settling tanks, while a second discharges from three to six times the dry weather flow to the storm-water tanks. The surplus flows over a weir to the stream outfall.

Rats, Fleas, and Plague in Japan. (Topi, pulci e peste in Giappone.) Guido Guerrini, Giorn. d. Reale Soc. Ital. d'Igiene. 1927, vol. 44, No. 1. 8 pp. Abstract by H. Harold Scott in *Tropical Diseases Bulletin*, vol. 24, No. 11, November, 1927, p. 933.

"This paper is largely statistical. Nearly half a million rats were examined during the 18 months from February, 1909, to July, 1910 Among this number 0.1 per cent of the *norvegicus* species were found infected with plague, but 1.55 per cent of *alexandrinus*. In Tokyo and Aichi the latter species was positive in 90.48 and 86.9 per cent, respectively; but in Prefecture of Miye *R.* [*M.*] *rattus* was positive in 53.68 per cent, *norvegicus* in 24.23, and *alexandrinus* in 22.09 per cent.

"As regards the fleas, *Ceratophyllus anisus* and *C. fasciatus* were widespread; *Paradoxospyllus curvispinosus*, a species peculiar to Japan, was very frequently met with, especially in Tokyo; *Xenopsylla cheopis* only rarely, in seaports; *Ctenopsylla cuniculi* common everywhere in the country. In Yokohama, among 2,508 fleas, there were 2,276, or 90.7 per cent, *C. anisus* and *P. curvispinosus* and only 9 of *X. cheopis* and *Pulex irritans* combined. Except *X. cheopis* all are most numerous in winter; they increase gradually from September to January, rapidly in January and February, and decrease rapidly in May.

"From examination of fleas caught in Yura all the species were shown to be carriers of plague except *Ceratophyllus felis*."

Residual Germicidal Action of Water Treated with Ultra-Violet Rays. E. C Berndt. *Journal of the American Association for Promoting Hygiene* and *Public Baths*, vol. 9, 1927, pp. 36–38. (Abstract by J. L. Robertson.)

The proper exposure of water to ultra-violet rays destroys bacterial life without adding odor, taste, or irritating qualities to the water. When used in connection with swimming pools, with re-circulating systems the results obtained are far better than the law of purification by consecutive dilution would indicate. According to this law, two turnovers of a pool water per 24 hours would indicate a removal of 63 per cent of the impurities. Tests made using ultra-violet ray sterilization show much better results.

Recent tests made at the Detroit Athletic Club, to determine whether there was any residual germicidal action imparted to water exposed to ultra-violet rays, showed better results with ultra-violet ray treatment than with the method of simple dilution by adding pure city water, although the bathing load was 20 per cent higher at the time when the tests were run on the ultra-violet process.

Recently the United States Bureau of Standards published a report on an investigation of the germicidal action of ultra-violet radiation. The following conclusion of this report is quoted in this article:

"It is important to emphasize that our results, in general, are in agreement with those of recent investigators, showing that the killing of bacteria by ultraviolet rays is not due to the small amounts of toxic chemical substances that may be produced by the action of the rays on the water or other medium."

Swimming Pool Sanitation a Public Health Problem. H. P. Croft. *Journal of the American Association for Promoting Hygiene and Public Baths*, vol. 9, 1927, pp. 34–35 (Abstract by J. L. Robertson.)

That the control of indoor and outdoor swimming pools by health authorities is desirable for the promotion of public health is evidenced by two States having statutory regulations; seven State health departments adopting rules and regulations; eight State health departments acting in an advisory capacity; and eight others preparing or considering the preparation of rules and regulations.

With the increasing popularity of swimming pools in amusement parks, public schools, etc., sanitary control is desirable. The committee on bathing places of the American Public Health Association has put forth tentative regulations. That part of these regulations relating to the bacterial quality of the water was stressed, with the thought that the bacterial content is influenced by all factors entering into the design, operation, and supervision.

California State Board of Health Rules Governing Sanitation, Safety, and Cleanliness of Swimming Pools. Anon. *Journal of the American Association for Promoting Hygiene and Public Baths*, vol. 9, 1927, pp. 65–78. (Abstract by R. E. Tarbett.)

The new rules were adopted in 1926 and cover the bacteriological quality of the pool water, cleanliness of pool water, sanitation of premises, sputum contamination (by requiring a scum gutter), diseased persons, dressing room and sanitary conveniences, safety of bathers, laundry, operating records and report, and application for permit. Notes accompanying the rules cover the question of construction, water supply, and water treatment, including disinfection and copper sulphate treatment.

Under the rules, applications must be made and permits granted by the bureau of sanitary engineering of the State board of health. Where construction is contemplated, a report including detailed plans must be submitted.

An Experiment in Mosquito-Proofing Barracks of British Troops. A. Campbell Munro. *Journal of the Royal Army Medical Corps*, vol. 49, No. 4, October, 1927, pp. 248–255. (Abstract by R. E. Tarbett.)

The article covers experimental screening of certain barracks at Lahore and Amritsar, plains stations in the Lahore Military District, India. These two stations are located in the flat country having poor drainage, and are the most malarious of all the Indian stations.

Antilarval work has been carried on for many years, as has personal protection by the use of mosquito nets, mosquito lotions, fumigations, etc. Not all of the barracks at these two stations were screened. Barracks screened were long, single story, bungalow type, having a veranda 12 feet wide on one side. These verandas were pierced by a series of archways, the only openings to the veranda. A stout wooden framework was made in each archway, covered with brass wire gauze, 16 mesh, over which one-half inch rabbit netting was nailed for protection. Doorways were double screened with a 10-foot screen gangway between the doors. Doors opened outward and were fitted with double springs. Windows were screened on the outside. Fireplaces were temporarily filled with brick during the warm weather and all ventilators covered with wire gauze. One man per barrack room was detailed for the sole duty of keeping screens in good repair. "It was made a court-martial offense to prop a screen door open or to pass a door so propped without removing the obstacle.

In addition to malaria prevention, other advantages were the dispensing with mosquito nets, which allowed the lowering of punkhas, the absence of flies and nonbiting insects as well as pest mosquitoes, and the actual lowering of the temperature in the rooms.

Malaria was as prevalent in the unscreened buildings at these two barracks in 1926 as in any other preceding year. During 1926 the malaria rate in the screened barracks in Amritsar was one-fourth the average rate for the three preceding years, and at Lahore one-fifth. At Lahore the rate was less than one-third the rate in the unscreened barracks.

The writer concludes that the screening of barracks properly carried out is a means of reducing malaria among troops, but can not be considered as a sole antimalaria measure, its efficacy being more or less in inverse ratio to the evening attractions outside the barracks.

Specifications and Analyses of Gravel and Filter Sand—Where Sand May Be Obtained. Lewis O. Bernhagen. Proceedings Ninth Texas Water Works Short School, January, 1927, pp. 169–172. (Abstract by W. M. Olson.)

Modern filter-plant operators must produce good water at low cost. The perforated underdrain system has resulted in economy in construction and operation, but demands extreme care in selecting and grading the gravel bed. Complete specifications for gravel are included. "Gravel should not have flat surfaces." Gravel should be uniformly graded, washed, and placed carefully in five layers, as follows:

Layer	Depth in inches	Size in inches
First	5½	1½ to 1
Second	5	1 to ⅝.
Third	4½	⅝ to ⅜.
Fourth	4	⅜ to 3/16
Fifth	3	3/16 to 10-mesh.

Filter sand should be round rather than sharp. Other specifications for sand depend upon the water to be handled. Complete specifications for sand for filtering an average water are given. The effective size should be from 0.35 to 0.40 millimeters, and the uniformity coefficient from 1.55 to 1.65. Depth of sand bed after washing to be at least 30 inches.

Suitable gravel may be found in Texas. "An almost ideal filter sand may be obtained at Red Wing, Minnesota." Native Texas sands need to be tested carefully to insure conformity to specifications. Sets of standard sieves may be obtained from chemical supply houses.

"Engineers should investigate local conditions with greater care than is usually exercised before recommending gravel and sand for a certain plant."

Determining Coagulant Dosage by Bottle Tests. Lewis I. Birdsall. Proceedings Ninth Texas Water Works Short School, January, 1927, pp. 264–265. (Abstract by W. M. Olson.)

River waters change rapidly in quality. These changes require corresponding changes in the amount of coagulant to be used in a water purification plant. Procedure is outlined for bottle tests to appraise the amount of coagulant required.

Prepare standard solution by dissolving 32.4 grams of coagulant in 1 liter of water. (One cubic centimeter contains one-half grain of coagulant.) Provide one-half gallon glass jars for water samples and 10 cubic centimeters pipette graduated to 0.1 cubic centimeter.

Add a measured amount of standard solution to several samples of water, shake vigorously, let stand until the floc has formed, and choose the most satisfactory treatment. Bottle experiments usually indicate a need for more coagulant than is necessary in actual operation.

DEATHS DURING WEEK ENDED JANUARY 28, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended January 28, 1928, and corresponding week of 1927. (From the Weekly Health Index, February 1, 1928, issued by the Bureau of the Census, Department of Commerce)

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Deaths for week ended Friday, Jan. 27, 1928.
[4] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

UNITED STATES

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 100 cities reporting cases used in the following table are situated in all parts of the county and have an estimated aggregate population of more than 31,620,000. The estimated population of the 94 cities reporting deaths is more than 30,900,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended January 21, 1928, and January 22, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
42 States	2,137	1,974	
100 cities	1,165	1,044	1,126
Measles:			
42 States	11,663	10,070	
100 cities	3,648	2,688	
Poliomyelitis:			
43 States	46	20	
Scarlet fever:			
43 States	4,846	5,633	
100 cities	1,626	2,284	1,450
Smallpox:			
42 States	1,161	843	
100 cities	133	121	118
Typhoid fever:			
43 States	198	255	
100 cities	37	41	51
Deaths reported			
Influenza and pneumonia:			
94 cities	1,201	1,183	
Smallpox:			
94 cities	0	1	
Kansas City, Mo	0	1	

City reports for week ended January 21, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during non-epidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year ealier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population, July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

[1] Typhus fever: 1 case at Savannah, Ga.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended January 21, 1928, compared with those for a like period ended January 22, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, December 18, 1927, to January 21, 1928—Annual rates per 100,000 population, compared with rates for the corresponding period of 1926-27 [1]

FOREIGN AND INSULAR

PLAGUE ON VESSEL

Steamship "Dryden"—At Liverpool, England, from ports on the La Plata River—Rodent plague.—The finding of seven plague-infected rats on the steamship *Dryden* at Liverpool, England, from ports on the La Plata River, Argentina, was reported January 20, 1928. The *Dryden* arrived at Liverpool January 5 and sailed for Glasgow, Scotland, January 15, 1928.

THE FAR EAST

Report for the week ended January 7, 1928.—The following report for the week ended January 7, 1928, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

India.—Rangoon, Bassein.
Ceylon.—Colombo.

CHOLERA

India.—Calcutta, Rangoon, Moulmein.
Straits Settlements.—Singapore.
Siam.—Bangkok.
French Indo-China.—Saigon-Cholon.

SMALLPOX

Egypt.—Suez.
India.—Karachi, Bombay, Cochin, Tuticorin, Madras, Vizagapatam, Calcutta, Rangoon.
Siam.—Bangkok.
French Indo-China.—Saigon.
Japan.—Moji.

Returns for the week ended January 7 were not received from Canton, China, or Vladivostok, Union of Socialist Soviet Republics.

BRAZIL

Rio de Janeiro—Communicable diseases—1926–1927.—Communicable diseases have been reported for the city of Rio de Janeiro for the year 1926 and the first six months of 1927, as follows:

Disease	Cases: Year 1926	Cases: January to June, 1927	Disease	Cases: Year 1926	Cases: January to June, 1927
Cerebrospinal meningitis	25	12	Plague	4	
Chicken pox	46	42	Poliomyelitis	1	2
Diphtheria	240	134	Scarlet fever		1
Dysentery	138	160	Smallpox	4,146	87
Influenza	37	34	Tetanus	1	2
Leprosy	25		Trachoma	2	
Lethargic encephalitis	1		Typhoid fever	243	89
Malaria	122	196	Whooping cough	9	18
Measles	21	58			

CANADA

Provinces—Communicable diseases—Week ended January 21, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended January 21, 1927, as follows:

Diseases	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Influenza	12							12
Smallpox				52		39	1	92
Typhoid fever	6	2	32	13		1		54

Quebec—Communicable diseases—Week ended January 21, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended January 21, 1928, as follows:

Disease	Cases	Disease	Cases
Chicken pox	53	Scarlet fever	114
Diphtheria	62	Smallpox	7
German measles	6	Tuberculosis	89
Influenza	4	Typhoid fever	32
Measles	161	Whooping cough	28

Quebec—Vital statistics—November, 1927.—Births and deaths in the Province of Quebec for the month of November, 1927, were reported as follows:

Estimated population	2,604,000	Deaths from—	
Births	5,746	Diphtheria	55
Birth rate per 1,000 population	26.48	Heart disease	307
Deaths	2,538	Influenza	35
Death rate per 1,000 population	11.70	Measles	11
Deaths under 1 year	697	Pneumonia	195
Infant mortality rate	121.30	Poliomyelitis	1
Deaths from—		Scarlet fever	19
Accidents (all)	74	Syphilis	2
Cancer	137	Tuberculosis (pulmonary)	160
Cerebrospinal meningitis	3	Tuberculosis (other forms)	36
Diabetes	28	Typhoid fever	23
Diarrhea	97	Whooping cough	29

St. John, New Brunswick—Health statistics—Lowered typhoid fever prevalence—Year ended October 3, 1927.—Information relative to health conditions at St. John, New Brunswick, Canada, shows a lowered typhoid fever prevalence, a total of 9 cases being reported for the city of St. John and 2 cases for the county, as compared with 13 cases for the city and 10 cases for the county reported during the previous 12 months. One typhoid-fever death was reported. This was stated as showing the first fatal case of the disease reported in three years. From 1920 to 1923 the average annual typhoid-fever

occurrence was 57 cases, and in the period 1924 to 1927 an average of 19 cases for each year.

Tuberculosis.—There were reported during the year 121 cases of tuberculosis with 66 deaths for the city and district. Of the deaths, 57 were of city residents, being 6 in excess of the tuberculosis deaths reported for the previous year.

Other communicable diseases.—Other communicable diseases reported were: Chicken pox, 56 cases; epidemic influenza and lethargic encephalitis, each, 2 cases with 2 deaths; measles, 12 cases; poliomyelitis, 1 case with 1 death.

Infant mortality—Child-welfare work.—Infant mortality reported at St. John, New Brunswick, during the year 1927 was stated to have been less than 90 per 1,000 living births as compared with a figure slightly in excess of 98 per 1,000 living births reported for the year 1926 and 151 for the year 1920. The improvement noted was attributed to efficient child-welfare work and personal visits of nurses to more than 800 infants, or more than two-thirds of the total population of under 1 year.

IRAQ

Cholera—December 18-24, 1927.—During the week ended December 24, 1927, 3 cases of cholera were reported in Iraq. The occurrence was in the city of Baghdad.

MADAGASCAR

Plague—November 1-15, 1927.—During the half month ended November 15, 1927, 112 cases of plague with 101 deaths were reported in the island of Madagascar. The distribution according to Provinces was as follows: Antisirabe, 8 cases, with 7 deaths; Itasy, 17 cases with 16 deaths; Moramanga, 7 cases with 6 deaths; Tananarive, 80 cases with 72 deaths, including Tananarive town with 9 cases, 7 deaths. The distribution according to type of disease was: Bubonic, 61 cases; pneumonic, 36 cases; septicemic, 15 cases.

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

TREASURY DEPARTMENT

PUBLIC HEALTH REPORTS

ISSUED WEEKLY

BY THE UNITED STATES
PUBLIC HEALTH SERVICE

VOLUME 43 :: :: NUMBER 7

FEBRUARY 17 - - 1928

SPECIAL ARTICLES

UNITED STATES
GOVERNMENT PRINTING OFFICE
WASHINGTON
1928

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

CONTENTS

PREVALENCE OF DISEASE

PUBLIC HEALTH REPORTS

VOL. 43 FEBRUARY 17, 1928 NO. 7

HEALTH CONDITIONS IN THE UNITED STATES, OCTOBER, NOVEMBER, AND DECEMBER, 1927

PREVALENCE OF DIPHTHERIA, INFLUENZA, MENINGOCOCCUS MENINGITIS, POLIOMYELITIS, SCARLET FEVER, SMALLPOX, AND TYPHOID FEVER

The preliminary reports of the prevalence of communicable diseases and the incomplete mortality data available for the fourth quarter of the year 1927 indicate in general unusually good health conditions in the United States. The general death rate was low as compared with previous years. The weekly death rates in large cities, compiled by the Bureau of the Census and published in the Public Health Reports, averaged about 2 per cent lower during these months than they did during the same months in 1926, and the figures for the quarter in 1926 were low. The large industrial insurance companies also experienced low death rates during the last three months of 1927.

In the comparisons given below of the reports for the years 1925, 1926, and 1927, preliminary telegraphic reports, received weekly from State health officers, are used for all three years. Final figures for 1927 are not yet available.

DIPHTHERIA

The increased prevalence of diphtheria which was noted during the first three quarters of the year 1927 continued during the fourth quarter. The number of cases reported in 1927 was greater than the number in 1925 or 1926, but the 1927 diphtheria rates are low when compared with the rates of a few years ago.

Comparisons of the case and death rates for diphtheria for the years 1916 to 1926, inclusive, were published in the Public Health Reports of October 7, 1927, page 2444.

During the last 13 weeks of the years 1925, 1926, and 1927, 37 States, with a population of about 90,500,000 in 1927, reported cases of diphtheria as follows:

	Cases
1925	22, 081
1926	26, 564
1927	27, 414

INFLUENZA

During the last 13 weeks of the years 1925, 1926, and 1927, 28 States reported cases of influenza as follows:

	Cases
1925	6, 972
1926	7, 777
1927	6, 747

These States had an aggregate population of about 62,800,000 in 1927.

The death rates for influenza and pneumonia are frequently relied upon to show the prevalence of influenza, as many cases of this disease are not reported. Weekly reports from 101 cities show an average death rate from influenza and pneumonia combined for the last 13 weeks of 1927 about 9 per cent below the average for the same period of 1926. The 1927 figures were lower than the 1926 figures for each of the 13 weeks except two.

MENINGOCOCCUS MENINGITIS

During the fourth quarter of 1927 more cases of meningococcus meningitis were reported than were reported during the same period of 1925 or 1926. It is possible, however, that some of the increase may be due to better reporting during 1927. The figures for 37 States for the 13 weeks from October 2 to December 31, 1927, and the corresponding period of the years 1925 and 1926, are as follows:

	Cases
1925	275
1926	364
1927	574

POLIOMYELITIS (INFANTILE PARALYSIS)

The 1927 epidemic of poliomyelitis reached its peak in September, but the incidence of the disease continued higher than usual until the end of the year.

Thirty-eight States, with an aggregate population of about 93,000,000, reported cases of poliomyelitis during the last 13 weeks of the years 1925, 1926, and 1927 as follows:

	Cases
1925	1, 124
1926	542
1927	3, 277

During the four weeks ended December 31, 1927, Massachusetts reported 55 cases of poliomyelitis; Ohio, 20 cases; Texas, 18 cases; and Illinois, 15 cases.

These figures are small as compared with those reported a few months earlier, but they are large for the month of December, and show that the effects of the increased prevalence lingered in widely

separated localities unusually late. On the Pacific Coast, where the seasonal prevalence of poliomyelitis is somewhat different from that elsewhere, California reported 64 cases of poliomyelitis during the last four weeks of December; Oregon, 43 cases; and Washington, 26 cases. In all of the States named above the incidence of the disease decreased during December.

SCARLET FEVER

During October, November, and December, 1927, the number of cases of scarlet fever reported to the Public Health Service was almost the same as the number reported for the same period of the year 1925, but the figures are somewhat smaller than they were for these months in 1926.

Thirty-seven States, having a population of about 90,500,000 in 1927, reported cases of scarlet fever for the last 13 weeks of the years 1925, 1926, and 1927, as follows:

	Cases
1925	33, 253
1926	38, 865
1927	33, 131

SMALLPOX

During the last 13 weeks of the year 1927, smallpox was more prevalent than it was during the corresponding period of 1925 or 1926. This condition is the result of neglect of vaccination, for it is possible to control smallpox by vaccination and revaccin tion.

The geographical distribution of the cases is very far from being uniform. As usual, the New England and Middle Atlantic States, with large and dense populations, had comparatively few cases of this disease.

The following table shows, by geographical groups of States, the numbers of cases of smallpox reported for the last 13 weeks of the years 1925, 1926, and 1927, by the State health officers of 38 States, with an aggregate population of about 93,000,000:

Smallpox cases reported for 13 weeks of 1925, 1926, and 1927 (October 2–December 31, 1927)

Geographic divisions	1925	1926	1927
New England	0	0	3
Middle Atlantic	5	162	94
East North Central	1, 054	1, 431	1, 427
West North Central	606	688	1, 729
South Atlantic	263	1, 065	507
East South Central	290	161	102
West South Central	302	533	727
Mountain	135	289	369
Pacific	1, 268	793	741
38 States	3, 923	5, 122	5, 699

TYPHOID FEVER

The preliminary figures for the year 1927 indicate that when the record is complete the typhoid fever case rate for that year will probably be the lowest ever recorded in the United States. The case rates and death rates for typhoid fever have been decreasing since comparable general statistics have been compiled.

The following table gives the annual typhoid fever case rates per 100,000 from 1917 to 1927, inclusive. These rates are based on the reports to the Public Health Service by State health officers, and the 1927 rate is based on preliminary reports.

Typhoid fever case rates per 100,000 population, 1917 to 1927, inclusive

Year	Number of States included	Cases per 100,000 population	Year	Number of States included	Cases per 100,000 population
1917	35	64	1923	47	32
1918	37	51	1924	45	33
1919	36	43	1925	46	42
1920	41	38	1926	46	36
1921	45	47	1927 (provisional rate)	36	26
1922	46	34			

During the last 13 weeks of 1925, 1926, and 1927, 36 States, having a population in 1927 of about 88,000,000, reported cases of typhoid fever as follows:

	Cases
1925	7, 912
1926	7, 574
1927	5, 600

POLIOMYELITIS IN THE UNITED STATES, 1927

During the year 1927 the incidence of poliomyelitis in the United States was higher than it was during any other year since 1916, when a widespread epidemic of the disease occurred.

The following table gives the poliomyelitis case rates per 100,000 population for the thirteen years from 1915 to 1927, inclusive. These rates are based on reports made to the Public Health Service by State health officers. The reports are not complete for any year, and the 1927 rates are based on preliminary figures, but the data appear to be sufficient to show general trends.

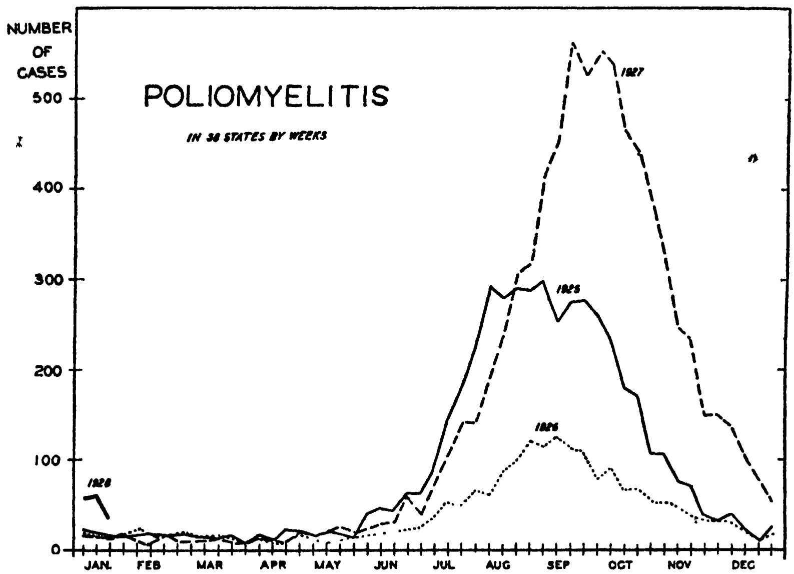
Poliomyelitis case rates per 100,000 from 1915 to 1927, inclusive

Year	Number of States included	Cases per 100,000 population	Year	Number of States included	Cases per 100,000 population
1915	22	3. 1	1922	39	2. 4
1916	27	41. 4	1923	40	3. 4
1917	30	5. 4	1924	38	5. 7
1918	34	2. 9	1925	44	5. 6
1919	32	2. 4	1926	40	2. 5
1920	36	2. 8	1927 (preliminary reports)	38	8. 4
1921	42	6. 9			

Weekly telegraphic reports from the State health officers of 38 States are available for the years 1925, 1926, and 1927. The aggregate population of these States was about 89,000,000 in 1925, 91,800,000 in 1926, and 93,000,000 in 1927. The accompanying chart shows graphically, by weeks, the numbers of cases of poliomyelitis reported by these 38 States for the three years and also for the first three weeks of 1928.

The aggregate numbers of cases of poliomyelitis reported for 52 weeks of each year are as follows:

1925	4, 903
1926	2, 074
1927	7, 784



Number of cases of poliomyelitis reported, by weeks, by 38 States for 1925, 1926, and 1927, and for the first three weeks of 1928

The chart shows that the aggregate number of cases reported was not sufficient to give warning of a general epidemic until late in July, 1927, although California, Louisiana, New Mexico, Arizona, and Texas reported more than the usual seasonal rise in the prevalence of poliomyelitis in June and July. This is in sharp contrast with the history of the epidemic of 1916, when New York State reported 345 cases of poliomyelitis in June and more than 4,000 cases in July.

In 1916 the peak of the epidemic was reached before the end of August, except in a few States, while in 1927 the peak was not reached until the middle of September, and the epidemic receded very slowly until after the first week of October.

The geographic distribution of the cases of poliomyelitis was irregular. This appears to be characteristic of the disease. In

1916 about half of the reported cases occurred in the State of New York, although the 26 other States which reported had almost six times the population of New York. In 1927 the States reporting the greatest number of cases were California, Massachusetts, and Ohio.

ELECTRON EQUILIBRIA IN BIOLOGICAL SYSTEMS

I. A METHOD FOR THE CONTINUOUS MEASUREMENT OF THE ELECTRICAL POTENTIAL IN LIVING CELLS

By Carl Voegtlin, *Professor of Pharmacology*, and Floyd De Eds, *Pharmacologist, Division of Pharmacology, Hygienic Laboratory, United States Public Health Service*

INTRODUCTION

All living organisms depend for their continued existence upon an external supply of energy. This energy is furnished in various forms: To plants as solar radiation; to animals almost entirely as so-called food, i. e., chemical energy. The utilization and transformation of this potential energy of food for the various needs of the animal has been and still is a fundamental biological problem. It is well known that this energy is made available by the gradual chemical disintegration of food to the end products of metabolism. Considerable information has accumulated concerning the nature of these complex biochemical reactions and the part they play in biological energy transformations. The interesting studies of Hill and Meyerhof on the energy transformations occurring during and following the contraction of skeletal muscle seem to indicate that the glycolytic process furnishes the energy for muscular contraction and that the energy required for recovery (restitution) is derived from the oxidation to CO_2 and H_2O of about one-fifth of the lactic acid formed during contraction.

In previous papers (1) (2) we have described some observations on spontaneously contracting isolated smooth muscle (guinea-pig uterus) which clearly showed that exposure of the muscle to substances such as glutathione, cysteine, cyanide, etc., produces sudden contractions. As proper precautions were taken to prevent changes in the hydrion concentration of the Locke solution, the contraction could not easily be attributed to changes in this factor. The suggestion was therefore made that the action of the above-mentioned substances is primarily due to their effect on an *oxidative* process of the muscle cells. It was furthermore pointed out that a proper correlation of oxidation-reduction potential and muscular contraction might materially assist in elucidating this problem. It was fully realized that the ideal procedure would consist in correlating muscular contraction with continuous measurements of the oxidation-

reduction potential (time : potential curves) by means of a suitable electrode method. Unfortunately, the conventional method used in physicochemical work could not be applied to the problem under consideration, for reasons which will be given later on. However, through the kindness of Professor Clark, of the division of chemistry of this laboratory, we were supplied with a series of oxidation-reduction indicators whose potentials had been determined by Professor Clark and his colleagues. These indicators and anthraquinone sulphonate (Connant) were used in some unpublished experiments by one of us (V.) with Mr. McClosky for the purpose of shifting the oxidation-reduction potential of smooth muscle and observing the effect on the contraction. Briefly stated, it was shown that the exposure of the muscle to equimolecular concentrations of the different indicators produced effects which could be predicted by the previous work and a knowledge of the position of a given indicator on the electrometric scale. These observations made it imperative to develop a suitable electrode method; for it was obvious that only time : potential curves could furnish the necessary details for a proper appreciation of the potential changes occurring during muscular contraction and relaxation.

Before proceeding with the description of this method it may be advisable to discuss briefly some of the fundamental principles involved in this work.

All forms of energy have a dual nature, being composed of the intensity and capacity factors. In the case of chemical energy,

Chemical energy = chemical potential × equivalent weight.

The chemical potential (intensity factor) is sometimes called the driving force of a reaction. The equivalent weight (capacity factor) is the quantity of a chemical which takes part in the reaction. In the case of electrical energy we have the equation—

Electrical energy = electrical potential × quantity of electricity.

The electrical potential (intensity factor) is measured as electromotive force (volts). Now it has been shown that the electromotive force is proportional to the chemical potential, and the electromotive force can therefore be used as a measure of chemical potential.

The interrelation of chemical and electrical energy is explained by the electron theory, which postulates the transfer of negative electric charges (electrons) in any chemical reaction. This being so we have used the word electron equilibria in the title, so as to bring our results into harmony with modern theoretical chemistry and physics.

The term oxidation has assumed a much clearer meaning in the light of the electron theory. The oxidation of a given element

or substance means simply the loss of one or more negative electric charges (electrons). For instance

$$Fe^{++} - e = Fe^{+++}$$

indicates the oxidation of ferrous ion to ferric ion, e being the symbol for electron.

Similarly, the oxidation of iron to ferrous ion can be written

$$Fe - 2e = Fe^{++}$$

The intervention of either oxygen or hydrogen in oxidations and reductions simply represents special cases of oxidation-reduction. It is possible to measure such oxidation-reduction reactions as

$$FeC_6N_6'''' \rightleftharpoons FeC_6N_6''' + e$$

by means of a suitable electrometric method.

DEVELOPMENT OF METHOD

Accurate potentiometric studies on biological systems are difficult for a number of reasons, but the most outstanding objections to current methods are the inability to follow continuously any potential changes originating within the system being studied, and the inability to follow such changes without drawing current from the system. The first objection means that a series of observations must be made, and the second objection demands that these observations must not be too close together. The second objection also prevents the accurate measurement of potential changes even though they be relative, because the withdrawal of current from the source results in polarization and a disturbance of the capacity factor.

It is one of the objects of this paper to describe an equipment which overcomes these difficulties. The apparatus permits the continuous observation of potential changes in a biological system without the withdrawal of current from the system. The possibility of such an equipment depends upon the modern three-electrode vacuum tube of the present day radio receiving set.

The use of the three-electrode vacuum valve in fields of endeavor other than the science of radio is not new. Höber (3), in 1919, had applied the three-electrode tube in his studies on the amplification of the action current of muscle. Daly and Shellshear (4), in 1920, employed the vacuum tube to amplify the movements of a string galvanometer in electro-cardiographic work. Forbes and Thacher (5) utilized the three-electrode tube to amplify the action currents of the frog sciatic. Gasser and Newcomer (6), in 1921, made use of the same principle in studies of the phrenic nerve. In 1922 Gasser and Erlanger (7) again applied the vaccuum tube in conjunction with a Braun tube for studies on nerve action currents. The chemists, as well as the physiologists, have had recourse to the advantages

offered by the three-electrode vacuum tube. In 1921 Noyes (8) described its use in measurements of the potential in an electrolytic cell for the deposition of iron. Goode (9), in 1922, and again in 1925, discussed the use of the tube in the construction of a continuous reading electrometric titration equipment. Calhane and Cushing (10), in 1923, used a vacuum tube circuit for the accurate titration of dilute salt solutions with silver nitrate. For a somewhat similar purpose Treadwell (11) employed a vacuum tube in 1925.

In all the above-mentioned work the three-electrode vacuum tube proved useful for one or more of the following reasons: Its ability to detect minute fluctuations in potentials, its ability to amplify such changes, and its ability to act in a properly constructed circuit without drawing current from the source under investigation. Before giving a description of the equipment used in studies of electron equilibria in biological systems, a brief description of the manner of action of the three-electrode vacuum tube will be given. For a complete discussion the reader is referred to the text of H. J. Van Der Bijl (12).

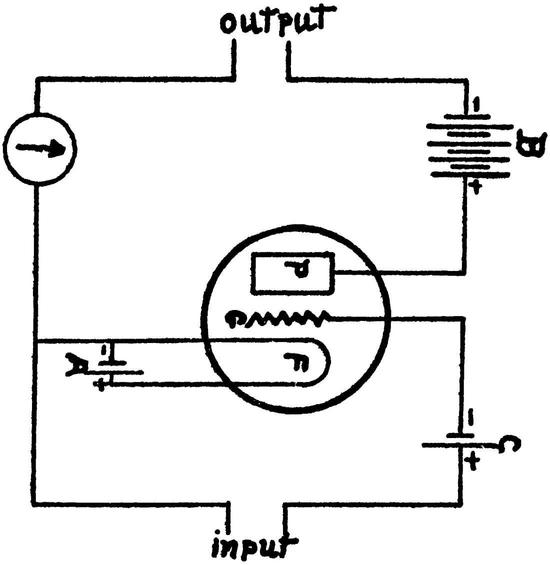


FIG 1 —A=6-volt storage battery; B=plate circuit battery (voltage value dependent upon the tube and its use); C=grid circuit battery (voltage value dependent upon tube and its use); F=filament of tube; G=grid of tube; P=plate of tube; FGG=grid circuit; PB=plate circuit

Input refers to connections leading to the source of potential being measured; output refers to connections leading to recording device.

When the filament F (Fig. 1) is heated by a current from battery A, there occurs an emission of electrons, some of which are drawn to the plate P by the positive charge imposed on plate P by the battery B. The current in the plate circuit is proportional to the number of electrons drawn to the plate and, hence, proportional to the positive charge imposed by B. A grid, G, is placed between the filament F and the plate P. Assuming a constant rate of electron emission from the filament F by virtue of a constant current from A, and assuming a constant positive charge on plate P, it follows that any variation in charge imposed on the grid G will result in an alteration in the number of electrons passing from the filament to the plate, i.e., an alteration in the plate circuit. For example, when the grid G is positively charged, the removal of electrons from the filament is

facilitated, and the current in the plate circuit is increased; but when the grid is negatively charged, electrons are repelled back to the filament, a smaller number of electrons reach the plate, and the plate current is consequently decreased. In other words, under the conditions of constant filament temperature and constant B battery voltage the current flowing in the plate circuit is a function of the current in the grid circuit.

If it is desired to use the tube in such a way that no current will be drawn from the source the potential of which is being measured, certain other considerations are of importance. When the grid becomes positive, there is an attraction of electrons to the grid and a current is set up in the grid circuit, for the resistance of grid circuit is no longer infinite. If, however, the source of potential causing fluctuations in the grid potential is superimposed upon a constant negative potential furnished by battery C, and large enough to keep the grid negative under all circumstances, the resistance of the grid or input circuit will remain infinite and no current will flow. Under these conditions the current in the plate circuit is a function of a variable grid potential, which always remains negative to the filament. This is a circumstance of the greatest importance for the measurement of potentials in biological systems, *for it meets the requirement of measuring potential variations without the withdrawal of currents from the systems of small capacity under investigation.*

Utilizing the principles so far discussed, a two-tube circuit[1] has been devised for the continuous measurement of the voltage changes taking place in spontaneously and rhythmically contracting tissue. The entire arrangement of the equipment is shown diagrammatically in Figure 2. For purposes of detail the vacuum-tube circuit is shown on a much larger scale than are the portions of the diagram relating to the potentiometer and the apparatus for supporting and recording the contractions of the tissue.

The various electrical connections are obvious from the diagram in Figure 2, but a few remarks concerning the choice of parts may be of interest. A single-tube equipment was used in the early part of the investigation, but the two-tube apparatus proved to have a greater range of utility. An equipment may be designed to use almost any type of tube, but in the set here described, storage-battery tubes were used, because a storage battery, preferably the lead type, of large capacity, about 150 ampere hours, supplies a more constant current to the tube filaments than is possible with tubes operated by dry cells. The first stage is supplied with UX 240 tube, because of its high amplification, while the second stage is equipped with a UV 201A. The plate or output circuit of the UX 240 tube feeds

[1] We express our appreciation to Dr. L. H. Adams, of the Geophysical Laboratory of the Carnegie Institution of Washington, for helpful suggestions in planning the two-tube arrangement.

into the grid circuit of the UV 201A tube through a variable ½ meg ohm resistance connected in series with a 22.5-volt C battery, the variable resistance acting as one of the controls for adjustment to maximum sensitivity. The millivoltmeter in the plate circuit of

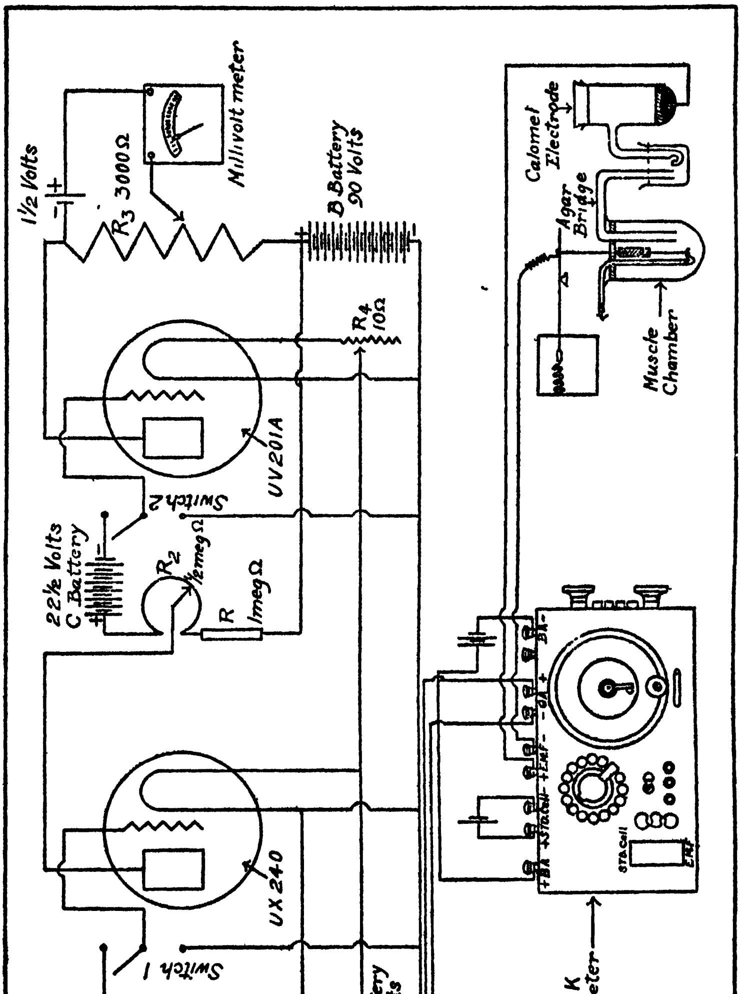

Fig 2.—Diagram showing connections of two tube equipment

the UV 201A tube is shunted by a 3,000-ohm variable resistance which acts as the second control for adjustment of maximum sensitivity.

By proper manipulation of the variable shunt resistance, R_3, and the two single-pole double-throw switches 1 and 2, it is possible to

adjust the apparatus without damage to the millivoltmeter. With switches 1 and 2 in the "down" position and all the resistance in R_3 cut out, the filament current is turned on. Switch 2 is now thrown to the "up" position and the desired zero point of the millivoltmeter adjusted by means of R_2 and R_3. Then switch 1 is thrown to the "up" position and the adjustment of R_2 and R_3 repeated, the sensitivity being greater the larger the amount of resistance used in the shunt R_3. The best results have been obtained with a filament voltage of 5.4, B battery voltage of 90, and C battery voltage of 22.5.

GENERAL CONSIDERATIONS CONCERNING THE APPLICATION OF THE METHOD TO BIOLOGICAL PROBLEMS

From the preceding discussion it is evident that functional changes in biological systems should be reflected by corresponding changes in potential. Furthermore, the selection of rhythmically contracting isolated smooth muscle for testing out the reliability of our new method has been exceptionally fortunate for the reason that the functional change is not complicated by the use of an external stimulus, as would be necessary, for instance, in work on isolated striated muscle. Moreover, the contraction of such smooth muscle as the guinea pig uterus is slow enough to permit a proper correlation of the contraction curve with the potential curve.

In order to determine the potential of the tissue it is of course essential to insert the electrode directly into the tissue. By the use of a careful technique the thin platinum wire electrode can be inserted with the least amount of injury. In fact the technique can be so refined that it should be perfectly feasible to use the method in conjunction with the microtechnique of Chambers for the study of the potential of single cells (ameba, nitella, etc.).

The arrangement for the study of the movements of the isolated virgin guinea pig uterus and segments of the rabbit intestine was essentially the same as that in the previous work (2). The platinum electrode consisted of a 32-gauge wire 5 cm. long. This wire was carefully coated with Bakelite with the exception of 1 mm. at one end (*a*) and 5 mm. on the other end (*b*). The Bakelite formed beads, and these made it possible to tie securely the uncoated end (*a*) of the electrode into the upper lumen of the organ by means of a strong silk ligature. End (*b*) of the platinum electrode was then connected by means of a very thin and very flexible gold wire to a small piece of modeling clay which was located 5 cm. from the fulcrum of a light heart lever. The end of the gold wire was firmly connected with the copper lead to the potentiometer. (Fig. 2.) Special care was taken to have a sufficient length of gold wire between point of attachment and copper lead so as not to interfere in the least with the movement of the lever. The lower end of the muscle preparation was securely

closed by a silk ligature and tied to the lower end of the glass tube through which oxygen was driven through the salt solution in which the muscle was suspended. A layer of liquid petrolatum, 1 cm. in thickness, was placed on top of the salt solution in order to prevent contact of the uncoated gold wire with the saline. The position of the muscle preparation in the bath was such as to insure complete immersion of the muscle in the saline bath at all times. The muscle lever was properly balanced and only sufficient weight was put on the muscle to take up the slack in the metallic and silk leads to the points of attachment.

The same arrangement was used for the experiments with isolated ventricular strips of the turtle's heart. The composition of the frog Ringer solution was as follows: NaCl, 0.6%; KCl, 0.0075%; $CaCl_2$ (anhydrous), 0.1%; $NaHCO_3$, 0.1%.

In the experiments with the turtle's heart *in situ* the platinum electrode was carefully tied into the apex and connected with the heart lever in the usual manner. One end of the agar bridge dipped into a cavity adjoining the heart, which was filled with frog Ringer solution.

A writing point of flexible photographic film was used in order to reduce the friction on the smoked kymograph paper to a minimum.

The voltage changes were read off by one person, and simultaneously recorded on the muscle curve by a second person and entered in the notebook by a third one. With this scheme the error committed in the correlation of potential curve and muscle curve was very small indeed. But it is obvious that continuous automatic registration of the potential curve is very desirable, in fact, essential for work with rapidly contracting organs. Preliminary experiments have shown that this is quite feasible and we shall report on this phase of the development of the method in a subsequent paper.

DISCUSSION OF PRELIMINARY RESULTS

Figure 3 shows a small section of a tracing of the rhythmic contractions (pendulum movements) of a duodenal segment of the rabbit. The lower line indicates time in seconds, up stroke indicates contraction of the muscle, and the figures represent millivolts. It was impossible to follow with the present technique more than the rough outline of the potential changes, but the high voltage value always was reached toward the end of relaxation and the low voltage at about the height of contraction. Attention is called to the great regularity of the potential changes coinciding with these rhythmic contractions, the maximum and minimum value differing only by 9 millivolts.

Figure 5 illustrates similar results obtained with a slowly contracting uterus. The lower line indicates time in seconds, the middle

line time signals of the potential readings, and the figures on the muscle curve again millivolts. The relation between muscle curve and potential curve is still better brought out by Figure 4. Both figures show clearly the relation between spontaneous rhythmic contractions and potential changes. There can be no doubt that the two phenomena are fundamentally related. It appears *that contraction sets in within a short time after the potential begins to fall and the voltage reaches its minimum value at the height of contraction. Then, as the muscle relaxes, the voltage is gradually built up again; and this process repeats itself with each contraction.*

Figure 6 represents one of the tracings obtained with the ventricular strip of the turtle's heart. Time is given in seconds. Here again

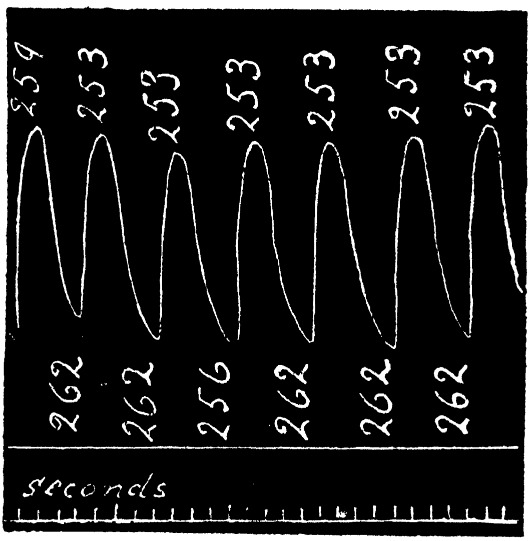

FIG. 3.—Rabbit duodenal segment

the same correlation is found between contraction and potential change.

Figure 7 illustrates a tracing of the turtle heart *in situ*. Time is in seconds. Up stroke represents contraction. During diastole the voltage is without exception 841 millivolts, and during systole 838—a difference of 3 millivolts. During the period indicated by the two arrows the vagus was stimulated by an induction current, with the result that the heart stopped contracting and the voltage increased by 6 millivolts (841 to 847). Twenty-four seconds after the vagus stimulation was stopped, the heart began to contract again and the same loss in voltage accompanying each contraction was again noted.[2]

[2] It appears that the method may furnish an explanation of the electrochemical cause of the electrocardiogram.

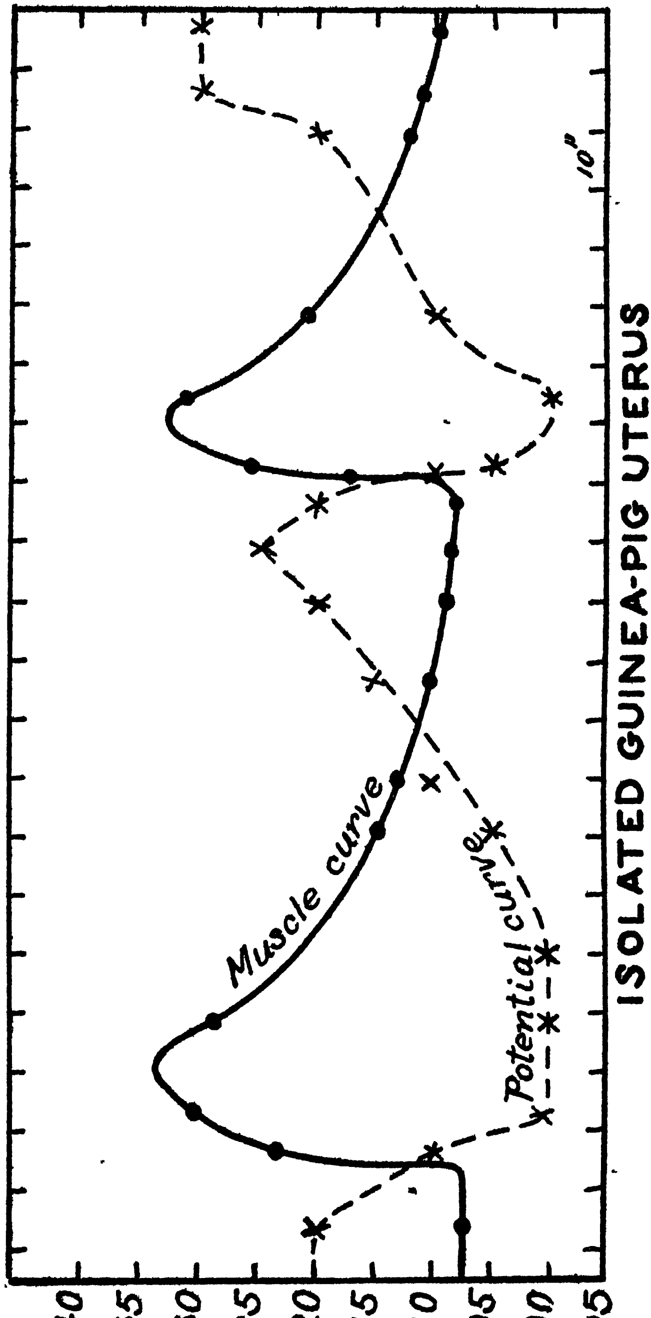

FIG. 4.—Relation between muscle curve and potential curve

Essentially the same situation was met in experiments in which the isolated gastrocnemius of the frog was stimulated through the sciatic nerve by a galvanic current. Here also contraction was accompanied by a loss of a few millivolts and relaxation by a return to the previous voltage.

Figure 8 illustrates an experiment designed to show the effect of changes in load on the potential. Time = 30 seconds. In this particular experiment a guinea pig uterus was put under a load of 3 grams, which is far in excess of the weight that the muscle could possibly lift. The voltage range fluctuated considerably without producing any contractions. At the time indicated by the arrow the muscle was released from the 3-gram weight, with the result that it immediately contracted and the voltage fell gradually from 660 with load to 365 millivolts after the load had been removed.

A similar experiment with the duodenal segment of the rabbit is illustrated by Figure 9. Time = 30 seconds. As far as the spontaneous contractions are concerned, the maximum voltage was always reached with relaxation, and the low voltage at the height of contraction, as in the experiment illustrated by Figure 3. The important new point, however, is the relation of the load to the voltage level. It is obvious that *the voltage level of the spontaneous contractions decreases with a decrease in load and increases with an increase in load.* This appears to be a fact of fundamental importance and is probably explained by the following line of reasoning. The work done by the muscle in lifting the weight during the spontaneous contractions is proportional to the weight if the contraction (distance) is of the same magnitude. In our experiment this is roughly true with the 1.5-gram, 1-gram, and 0.5-gram load. Now, there must be some relation between the chemical energy expended and the mechanical work performed by the muscle and an increase in work can be obtained only by an increased consumption of chemical energy. This latter, as we have seen, is—

$$\text{Chemical energy} = \text{chemical potential} \times \text{equivalent weight.}$$

Now the potential change occurs immediately after reducing the load or increasing it. An increased chemical potential immediately establishes conditions for increased mechanical work, for the potential is the driving force of chemical reactions. We are not in a position to give any information as to the changes occurring in the other work factor—the capacity. But very probably the chemical capacity (equivalent weight), being represented by the chemical constituents of the muscle, is not likely to be subject to such sudden alterations. We shall return to the discussion of this subject in a future communication; but we should like again to draw attention to Figure 8.

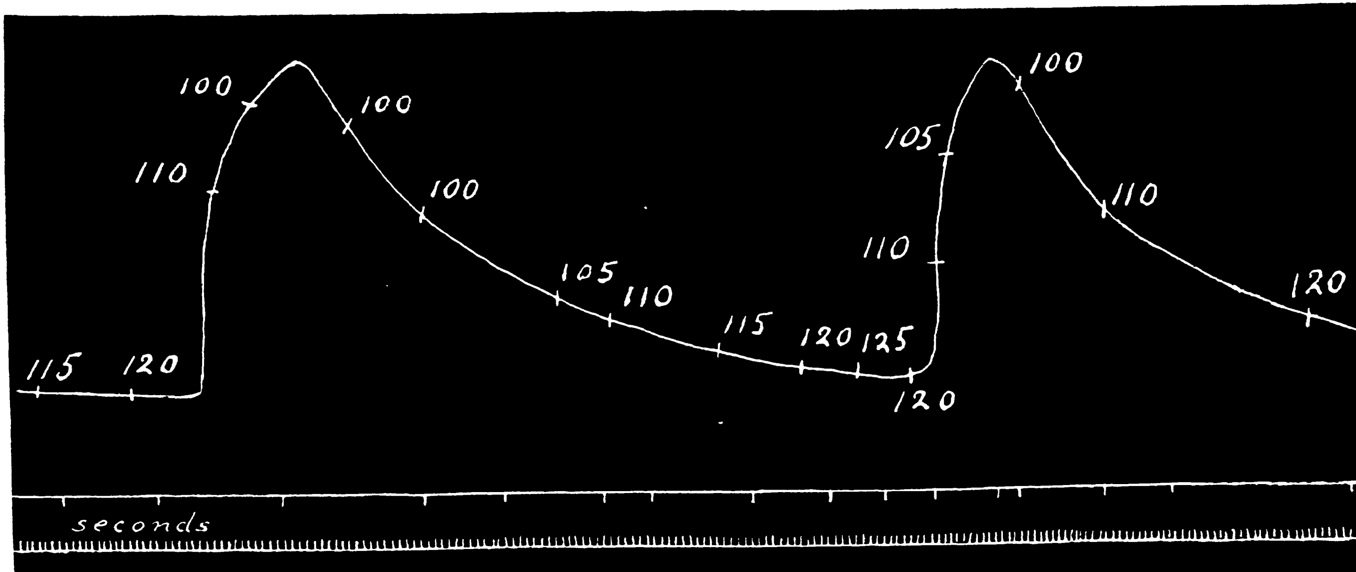

Fig. 5.--Guinea pig uterus. Spontaneous contractions and potential changes

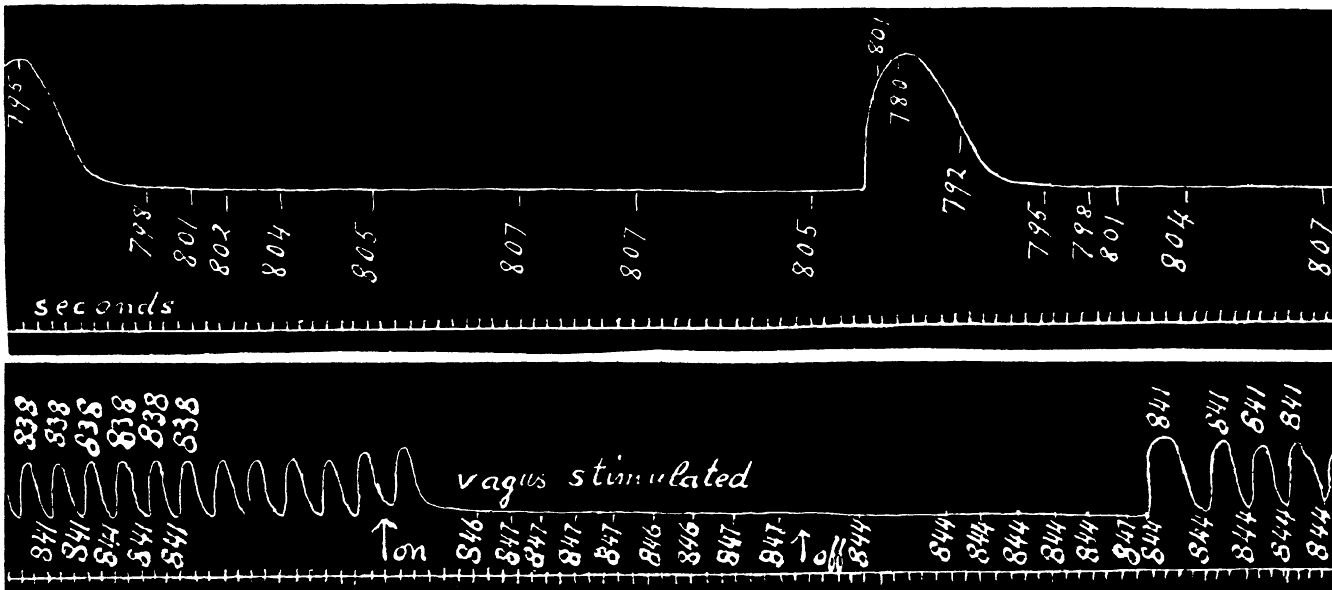

Figs. 6 and 7 —Upper graph is tracing obtained with ventricular strip of turtle's heart, lower shows tracing of the turtle heart in situ

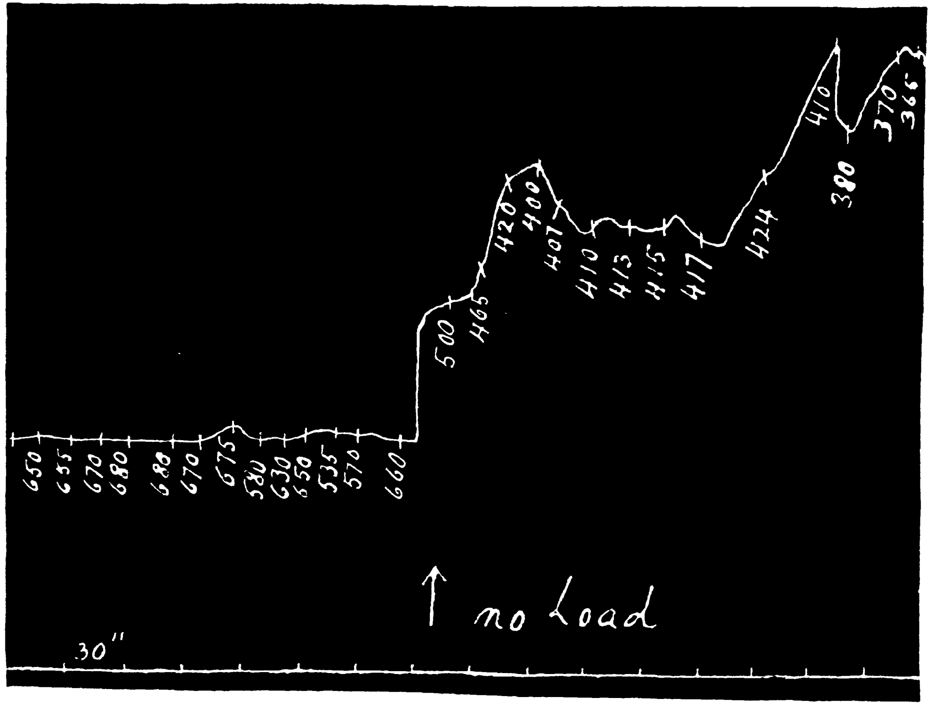

Fig. 8.—Guinea pig uterus. Effect of taking off 3-g. load

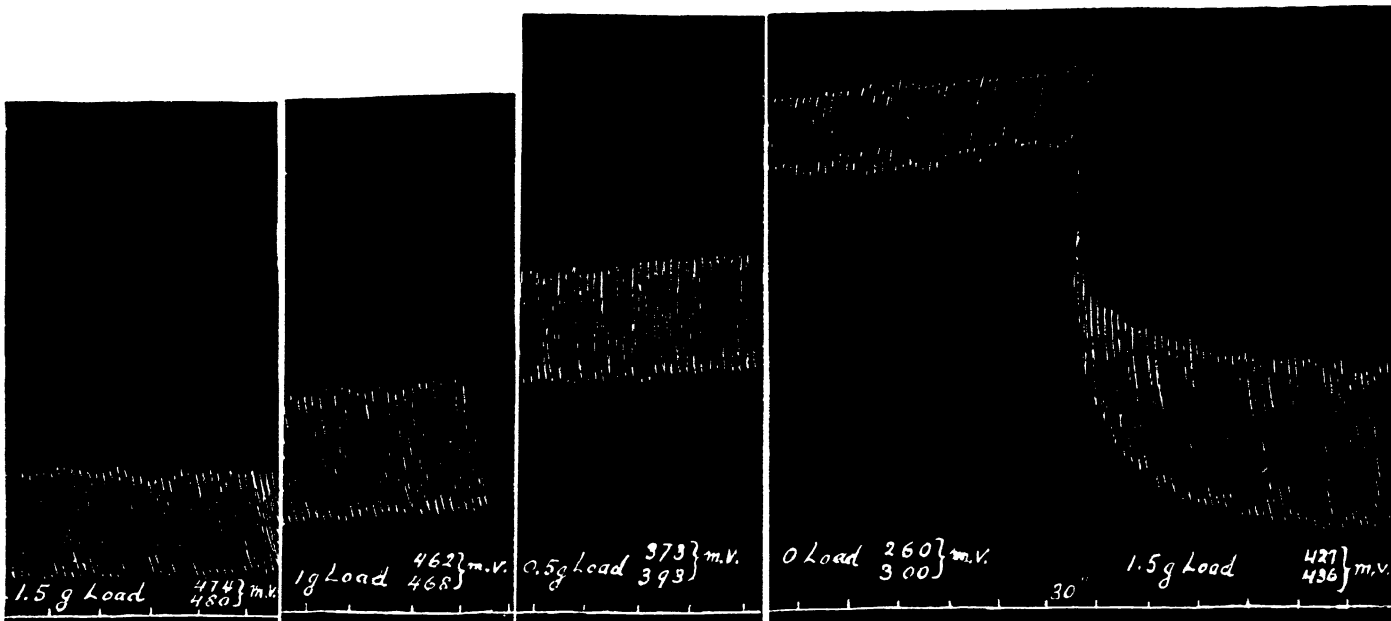

Fig. 9 —Tracing of rabbit duodenal segment Effect of variation of loading

The uterus under an excessive load shows potentials which are very high indeed, although the muscle is not showing any appreciable spontaneous contractions. What is the explanation of this large increase in voltage resulting from heavy loading? The muscle does no external work, but nevertheless it must expend a large amount of energy in maintaining the weight at a given height. It appears that this demand for additional energy is met by the large increase in potential, or, to put it in other words, the "driving force" of the chemical reactions of the muscle tissue is increased.

The results which have been reviewed indicate that our new method reveals with great constancy a relation between potential change and functional change of a great variety of different living structures. We emphasize again that the arrangement does not involve withdrawal of current from the tissue, and, what is equally important, the observations made on the spontaneously contracting muscles are not complicated by the application of an external stimulus. For these reasons we believe that, due to fortuitous circumstances, we have selected the ideal conditions for testing out the reliability of the method for the study of biological problems. The relatively few experiments described throw a new light on muscular contraction, tonus, and physiological rhythm, and electrochemical studies of this sort will assist in the solution of many biologic puzzles.

We have refrained from interpreting the observed potential changes as changes in oxidation-reduction potential. Our equipment, consisting essentially of the set-up, voltmeter—platinum electrode—unknown potential—saline--agar bridge—calomel electrode—voltmeter, can be used to great advantage by the physical chemist for the determination of oxidation-reduction potentials of nonliving systems. Applied to biological systems, however, the method may or may not indicate oxidation-reduction potential pure and simple. The reasons for the justification of this standpoint will be discussed in the next paper. We feel justified, however, in using the method for the study of electrical potential irrespective of any given type of chemical potential which may be involved. In fact, we have been bold enough to use the title "electron equilibria," *because acid-base equilibrium, oxidation-reduction equilibrium, etc., all involve electron equilibria and are therefore interrelated.*[3] It seems, therefore, far better to begin work of this nature from the broadest aspect possible and to proceed then to a more detailed analysis.

It is obvious that the method has opened up a vast field of research in the fundamental medical sciences and in biology in general.

[3] We call attention to the fact that considerable confusion exists in this matter even in the recent literature on physical chemistry. This is due to a lack of proper perspective and the use of improper definitions.

SUMMARY

1. The need for a method for continuously following the electrical potential differences in biological systems is discussed.

2. The three-electrode vacuum tube is briefly described and shown to fulfill the requirements of making possible the measurement of potential changes without the withdrawal of current from the biological system.

3. A two-tube equipment is briefly described and all electrical connections are shown diagrammatically.

4. The basic principles for the applications of the method in biological studies are discussed.

5. Preliminary experiments with spontaneously and rhythmically contracting isolated smooth muscle, heart muscle, and electrically stimulated skeletal muscle indicate that contraction is accompanied by a decrease, and relaxation by an increase, in electrical potential. Rhythmic contractions are correlated with rhythmic potential changes and furnish a new interpretation of physiological rhythm and muscular contraction.

6. The method is suitable for the general study of the relation between function and electrochemical changes in living cells.

INFANT MORTALITY FROM DIFFERENT CAUSES AND AT DIFFERENT AGES IN NINE CITIES OF THE UNITED STATES [a]

By Selwyn D. Collins, *Associate Statistician, United States Public Health Service*

Infant mortality and its causes continue to occupy an important place in public health discussions. In the birth registration area of

[a] Some of the data included in this paper were originally prepared for and presented by a Public Health Service representative to the Office International d'Hygiène publique.

the United States infant mortality (deaths of infants under one year of age per 1,000 live births) has decreased from 100 in 1915 (the year the birth registration area was organized) to 71 in 1924. This is the remarkable decrease of 29 per cent. The death rate under 1 year of age per 1,000 persons decreased about 32 per cent from 1901 to 1920 in the United States.[1]

Infant mortality in the State of Massachusetts decreased from 170 in 1875 to 68 in 1924, a decline of 60 per cent in the half century.

Similar decreases could be cited for England, New Zealand, and almost any other important country of the world.

In recent years, however, there is a tendency toward a slackening of the decline. The rate for the birth registration area of the United States for the years 1925 and 1926 actually showed slight increases over 1924, the 1926 rate being slightly higher than the 1925. Such a tendency is inevitable as the rate approaches a more or less irreducible minimum—at least irreducible without new methods of attack upon the problem of infant mortality. Inasmuch as there is a tendency toward a slackening of the rate of decline, it behooves public-health workers to analyze the infant mortality more carefully. Two refinements suggest themselves in this matter: We may look more carefully into (*a*) the ages at which infants die and (*b*) the causes of death.

In considering the age group under 1 year as a whole, it may seem that the data have been sufficiently refined with respect to age. However, during the course of the first year a baby about trebles his weight and increases considerably in height. The actual increases in weight and in height from birth to 1 year of age are as great as in the period of rapid growth just before puberty, and the relative or percentage increase in these measurements is far greater during the first year of life than at any other period. The first year is, then, a very long one as judged by the baby's development and changes in his life during the period. Looking at the matter from this viewpoint, infant mortality becomes a very crude measure of what happens to the infant—as crude, comparatively, as the death rate at all ages combined which we have called the "crude" rate in contrast to the "adjusted" rate which takes account of differences in the age distribution of the peoples whose death rates are to be compared.

When all causes of death are considered as a whole, we are considering deaths from diarrhea and enteritis, measles, tuberculosis, etc., which causes appear to be associated with the baby's postnatal existence, together with deaths from premature birth, congenital malformations, etc., which appear to be more closely related to the

[1] Britten, R. H.: Some Tendencies Indicated by the New Life Tables. Pub Health Rep, vol 39, No. 15, Apr. 11, 1924. (Reprint No. 912.)

prenatal period of the baby's life than to anything which takes place after its birth.

What, then, is happening to the death rate of infants under 1 week of age, 1 week to 1 month of age, and 1 month to 1 year; and what is happening to the death rate from premature births, congenital malformation, etc., as compared with the death rate from diarrhea and enteritis and infectious diseases?

TREND IN INFANT MORTALITY

In Figure 1 infant mortality rates for Massachusetts, New Zealand, and the United States registration area [2] have been plotted on a semilogarithmic chart to indicate the trend. On such a chart an equal distance vertically represents an equal relative or percentage change in the rate, and the slope of the line, therefore, indicates the proportional change in the rate. The top continuous line in Figure 1 represents the total infant mortality under 1 year of age in Massachusetts from 1870 to 1926. The dotted line at the top shows the same rate for the whole United States birth registration area since its organization in 1915. The two rates are very nearly the same, and the Massachusetts data may be assumed to represent fairly well the trend in the United States. The New Zealand total infant mortality rate is much less than that in Massachusetts or in the United States birth registration area and has been less during the past 50 years; but the general trends of the New Zealand and the Massachusetts curves are roughly parallel, indicating that the percentage decrease in the infant mortality has been about the same in the two countries.

At the bottom of the graph is a line representing the mortality under 1 month of age in New Zealand. This rate is about the same today as it was 50 years ago. Similar data are not available in the earlier Massachusetts reports; but since 1916, when such data became available for the United States birth registration area, the decline has been much less than that in the total infant mortality rate. If deaths under 1 week are considered, the decline has been still less, and deaths under 1 day do not seem to have declined at all.

Another line for New Zealand in Figure 1 represents deaths due to causes associated with early infancy. These deaths nearly all occur under 1 month of age, but the two groups are not identical. The trend, however, is the same—there has been little or no change in the rate for these causes in the past 50 years.

The death rate for causes associated with early infancy is shown for Massachusetts from 1901 to 1926. Although there has been some

decrease in deaths from these causes, the decline is much less than in the total infant mortality.

Pirquet [3] has shown that in England and Wales the death rate during the first month of life had decreased very little; all the decrease in infant mortality has been in the ages over 1 month of age. Dublin [4] has pointed out that while infant mortality after the first month of life has decreased a great deal in the past 20 years the mortality of the first month of life has remained nearly the same throughout that period.

Woodbury [5] has shown that in the birth registration area of the United States infant mortality from malformations increased 10 per cent and from injury at birth increased 23 per cent from 1915 to 1921, although during the same period infant mortality from all causes decreased 21 per cent, diarrhea and enteritis decreased 34 per cent, respiratory diseases decreased 32 per cent, and in general other diseases important in the later months of the first year of life decreased considerably.

It appears, then, that infant mortality, as a whole, has been decreasing, but the mortality of early infancy has long been at a standstill, apparently unaffected by measures that have been taken to reduce infant mortality.

INFANT MORTALITY IN DIFFERENT CITIES

In different cities of the United States the infant mortality rate varies considerably even when cities of approximately the same size are compared. The question arises as to which causes of death are chiefly responsible for the difference. Is the variation chiefly in the early deaths which are presumably tied up with prenantal conditions or is it in the later months of infancy when postnatal conditions presumably have more influence on mortality?

The nine cities for which the data are given are all within the class of 100,000 to 600,000 population and range from the lowest to the highest in this country in infant mortality rates. These nine cities were selected solely on the basis of the size of the total infant mortality rate.

The infant mortality rate for Pittsburgh applies to the white population only; in the other cities the rate is for the total population. Pittsburgh is the only one of these cities with any large number of negroes.

TABLE 1.—*Populations, infant mortality rates, and birth rates in nine selected cities of the United States*

City	Population, census of 1920	Number of births, 1922–1924	Infant mortality rate per 1,000 live births, 1922–1924	Number of married women 15–54 years of age, 1920	Number of births, 1920	Birth rate per 1,000 married women 15–54 years of age, 1920	Birth rate per 1,000 total population, 1920
Seattle, Wash	315,312	16,032	48.5	62,978	6,166	97.9	19.6
Minneapolis, Minn	380,582	29,012	53.8	70,226	9,182	130.7	24.1
Portland, Oreg	258,288	15,435	54.2	51,667	5,202	100.7	20.1
San Francisco, Calif	506,676	26,366	56.6	90,958	9,034	99.3	17.8
Akron, Ohio	208,435	14,015	65.6	39,798	5,395	135.6	25.9
Rochester, N. Y	295,750	19,646	68.3	54,434	6,716	123.4	22.7
Pittsburgh, Pa	[1] 588,343	[2] 42,222	[2] 90.5	[2] 94,976	[2] 13,912	[2] 146.5	[2] 25.3
New Bedford, Mass	121,217	9,809	96.5	21,777	3,507	161.0	28.9
Fall River, Mass	120,485	10,772	103.8	19,403	3,537	182.3	29.4

[1] Includes 38,082 colored persons. Rates for Pittsburgh are for white only. For all the other cities the rate is for the total population, since none of the cities includes any large number of colored. Deaths for 1922 in these cities were not given by cause, age, and color.
[2] White only.

It is fully realized that these cities are not comparable. Pittsburgh is a "steel" town, with a population composed of many races; Fall River is a "textile" town; Minneapolis a flour-milling center of the agricultural Northwest. Again, these cities differ climatically. San Francisco is cooler in summer and probably warmer in winter than most of the other cities.

But no matter how different the conditions in these nine cities may be, it would seem legitimate to compare infant mortality at different ages and from different causes to see if the rates in these different subgroups run along with the total rates or whether the differences between the cities show up only in certain age periods and for certain causes of infant mortality. In Table 2 and Figure 2 a comparison of the rates in the nine cities is made for all ages and for the three age periods, under 1 week, 1 week to 1 month, and 1 month to 1 year.

NUMBER OF DEATHS				
Seattle, Wash	777	390	86	301
Minneapolis, Minn	1,561	782	233	546
Portland, Oreg	836	449	104	283
San Francisco, Calif	1,493	644	200	649
Akron, Ohio	919	376	123	420
Rochester, N. Y	1,341	596	178	567
Pittsburgh, Pa	3,821	1,299	499	2,023
New Bedford, Mass	947	290	115	533
Fall River, Mass	1,118	351	92	675

The rates in all cases are per 1,000 live births without any reduction to an annual basis. The annual death rate under 1 week would really be about fifty-two times the rates given here, or something like 1,500 per 1,000; in other words, if deaths continued at the rate they occur during the first week of life all the infants would die before they reached their first birthday. However, we are interested only in a comparison as between the cities, and as long as we compare rates for the same age period the different cities may be compared without reducing the rates to an annual basis.

In the top section of the graph the actual rates are shown; in the lower section they have been put on an index basis by dividing the rate for each city by the rate for Seattle, the city of this group having the lowest total infant mortality rate during the three years 1922–1924. In the age group under 1 week there is relatively little difference in the rates in the nine cities, the highest rate being only 34 per cent greater than the rate for Seattle. The age group 1 week to 1 month varies somewhat more; and when we turn to the age group from 1 month to 1 year of age there is a great deal more variation. In this latter age group the rate for Fall River is 234 per cent higher than the rate for Seattle, the rate for Pittsburgh is 155 per cent higher, and the rate for New Bedford is 190 per cent higher than the Seattle rate. Nearly all of the large differences in the infant mortality rates of these cities are in the rates over 1 month of age; the rates under 1 week are relatively constant. The geographical position, climatic conditions, racial stock, industrial conditions, and many other

important factors are widely different for these nine cities, and yet the infant mortality under 1 month of age remains relatively constant.

No doubt the activities for the conservation of infant lives by health agencies in these various cities are widely different, yet the

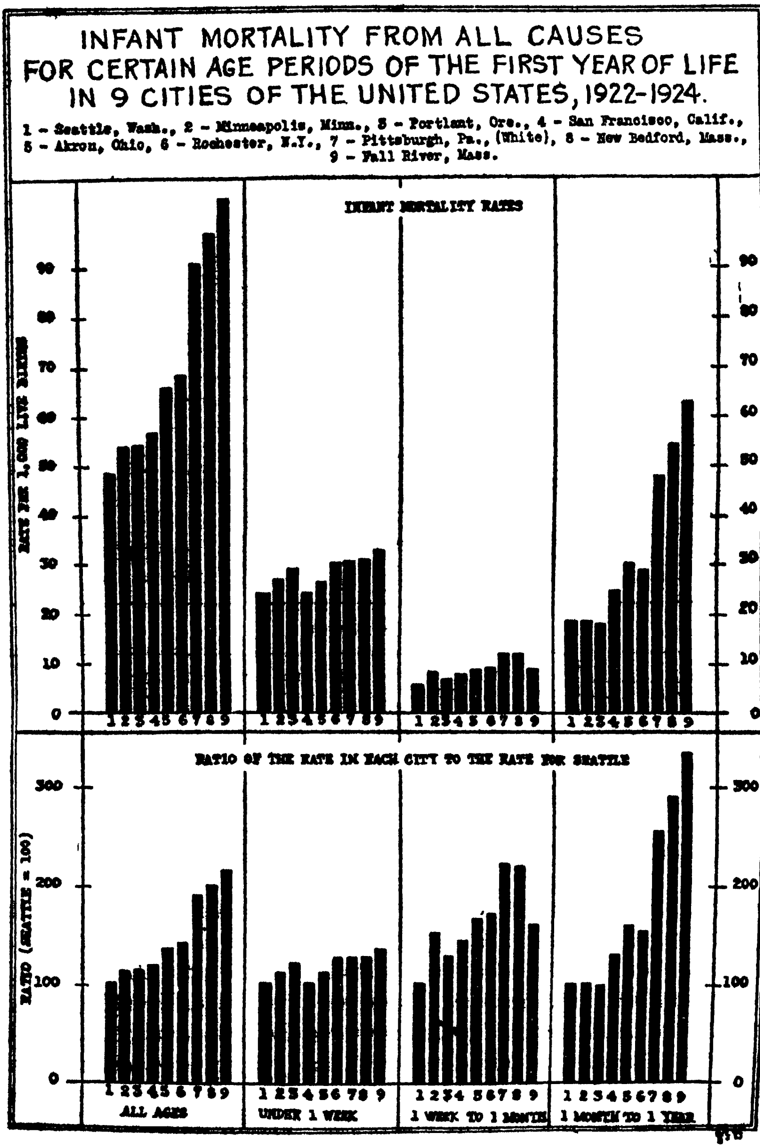

FIG. 2

death rates under 1 week of age are not at great variance. Evidently such measures as are at present taken to save infant lives have had little effect on deaths under 1 week of age.

[1] Including measles, scarlet fever, whooping cough, and diphtheria.
[2] Including dysentery, erysipelas, meningococcus meningitis, and tetanus.

Table 3 and Figure 3 show infant death rates in the nine cities from different causes. The upper section shows actual rates and the middle section shows indices computed by dividing the rate for each city by the rate for Seattle. Diarrhea and enteritis stand out as the cause of death, which varies most in the different cities, but the infectious diseases of children and the respiratory diseases also show considerable variation from city to city. The group of causes at the right of the graph, congenital malformations, congenital debility, premature birth, injury at birth, and other diseases of early infancy, show relatively little variation in the different cities.

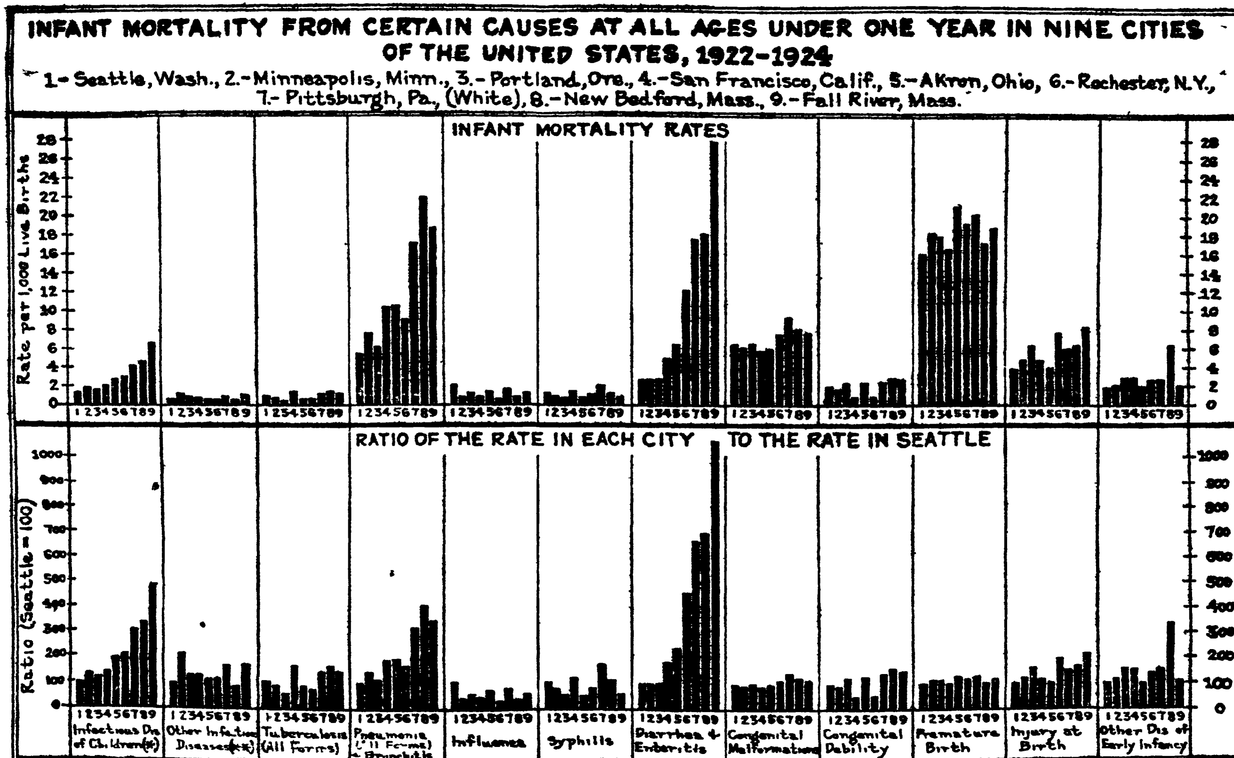

FIG 3

* Includes measles, scarlet fever, whooping cough, and diphtheria. ** Includes dysentery, erysipelas, meningococcus meningitis, and tetanus.

Deaths from the causes which vary least in the different cities occur largely during the first month of life. Figures 2 and 3 reflect the same conditions.

The great problem of neonatal infant mortality remains before us and its fundamental causes appear to be the same throughout the civilized world.

COURT DECISIONS RELATING TO PUBLIC HEALTH

City held not liable for use of land as garbage dumping ground by city scavenger.—(Mississippi Supreme Court, Division B; City of Laurel *v.* Ingram, 114 So. 881; decided December 12, 1927.) An action for damages was brought against the city of Laurel on account of the use of plaintiff's land as a dumping ground for the garbage of the city. The city employed a scavenger to remove and dispose of garbage and other refuse matter, including dead animals, from residences and business places, as well as the city garbage and refuse proper. Fees for the scavenger's services were fixed by the city, and were paid by the property owners to the scavenger. The charges for the removal of the city garbage proper were paid by the city itself. The scavenger was to provide his own dumping ground, and the city retained no control over him as to how or where he should dispose of the garbage. The plaintiff recovered in the lower court and the city appealed. The supreme court took the view that the city was not liable, basing its decision on the ground that the scavenger was an independent contractor. The court said:

If the city scavenger, in the present case, was an independent contractor, it is wholly immaterial whether appellant, in providing for the disposition of garbage and dead animals, was acting in its governmental, or in its private corporate

capacity. In either case, there would be no liability on the part of appellant for the damage done appellee's land by the scavenger in the performance of his work. The selection of the dumping ground would not be the act of appellant, but the act of the scavenger, the independent contractor, for which the latter alone would be liable to any person thereby injured.

We see no escape under the undisputed facts of this case from holding that the city scavenger was as much an independent contractor as the sanitary contractor was in the Shepperd Case. Knowledge on the part of the city authorities that the city scavenger was trespassing on appellee's property did not make the appellant liable; nor did the fact that, when appellee made complaint to the mayor of what was being done, the latter undertook to stop the practice. The mayor could not bind appellant in that manner. He had no right to direct the scavenger where to dump the garbage and dead animals.

Collection of ashes and rubbish held to be a governmental function.—(Ohio Court of Appeals, Cuyahoga County; Gorman *v.* City of Cleveland et al., 159 N. E. 136; decided May 2, 1927.) The plaintiff brought an action against a street railway company and the city of Cleveland to recover damages for injuries received while he was a passenger on a street car. It appeared that, while the plaintiff was attempting to alight from a street car, the car was struck in the rear by a city truck used to collect ashes and rubbish from residences and business places within the city, and that the plaintiff was injured when the sliding door on the street car closed upon his foot. The trial court rendered judgment in favor of the city on the ground that the collection of ashes and rubbish was a governmental, and not a proprietary, function. The court of appeals affirmed the judgment of the lower court.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Summer Camps in Pennsylvania. H. M. Freeburn, *Public Health News*, New Jersey State Department of Health, vol. 12, No. 5, April, 1927, pp. 118–120. (Abstract by E. C. Sullivan.)

This article, which is a part of a paper read before a meeting of the New Jersey Sanitary Association on December 3, 1926, summarizes some of the work done by the Pennsylvania Department of Health in the supervision of summer camps. The work of inspecting such camps has rapidly increased; and since many of the camps are occupied by children, every effort is made by the bureau of engineering of the State Health Department to have such camps placed in a sanitary and healthful condition.

With the increased use of automobiles, dangerous water supplies and insanitary conditions along roads have become a greater menace than heretofore with respect to the possibilities of typhoid fever being contracted at road side stands and camps and being carried back to the cities. The problem has been handled in Pennsylvania by the establishment of a fully equipped bacteriological laboratory on a motor truck, detailed surveys of such supplies along highways, and the placarding with signs stating whether or not the water supplies are safe. Tourist camps have been included within the scope of this work.

The article gives the rules and regulations of the Commonwealth of Pennsylvania governing the establishment of camps, defining the word, and outlining the necessary requirements for their establishment and maintenance.

Estimation of Lighting in Schools. Anon. *The Medical Officer*, No. 986 (vol. 37, No. 25), June 18, 1927, p. 285. (Abstract by C. L. Pool.)

Lighting Birmingham schools was studied by comparing the illumination received on a screen in a given position with the illumination received from the whole hemisphere of the sky. The ratio was obtained by referring each reading to the illumination from a standard lamp. A coefficient of 0.01 indicates that the light received at a given point is equal to one-hundredth part of the light available from the total sky.

Readings were made near the middle and at the worst lighted parts of the room. Average readings varied from coefficients 0.0014 to 0.02 and "worst" readings from 0.00043 to 0.077. Standards were suggested for "good," "fair," "poor," and "bad lighting"—i. e., good lighting being indicated by coefficients of 0.02 (or above) to 0.007 in the middle of the room, and coefficients of 0.007 (or above) to 0.003 at the worst lighted points.

Poisoning by Carbon Monoxide Gas from Heaters, Motors, Etc. C. E. B. Waldron. *Health Bulletin*, State of Victoria, Australia, No. 10, April–June, 1927, pp. 311–319. (Abstract by Leonard Greenburg.)

The author of this paper describes the various means by which carbon monoxide is formed, and reiterates the fact that the ordinary gas heater may be a producer of carbon monoxide under certain conditions. Due to its extremely poisonous character, and the fact that it is colorless and odorless, carbon monoxide is a very subtle poison. Every bathroom in which a gas heater is installed, the author says, should be equipped with ample, permanent inlet and outlet ventilation, the inlet ventilation by an external wall vent situated just above the floor level, and the outlet vent about 1 foot below the ceiling. The flue of the gas heater should be carried through the roof space to the open air and cowled so as to prevent down drafts. Care should be exercised in locating the ventilating pipe to insure an up current, and for at least 4 feet the pipe should be vertical. In the absence of these precautions the room door and window should be left open.

The insidious onset of the effects of carbon monoxide are described and the symptoms presented in some detail. First-aid measures include the removal of the gassed victim and the use of emetics if the person is conscious. The administration of artificial respiration and the use of stimulants are described.

Report on the Working of the Corporation of Madras Water Analysis Laboratory for 1926. S. V. Ganapati. 62 pages. (Abstract by R. E. Thompson.)

Extensive tabulated analytical data are given. Consumption during the year was 15–19 m. g. per day, of which 12.73 m. g. was treated by slow sand filtration, the deficiency being made up with raw water from Red Hills Lake, the source of supply, which was chlorinated during the period July to December. There are 17 filters, 14 of 1 m. g. d. capacity and 3 of 1.33 m. g. d. capacity. Average length of filter run was 18 days, efficient length of run as regards rate of filtration being 10 days. Production of hydrogen sulphide in all beds continued to be a disconcerting feature, persisting even when chlorinated water was applied to filters. The water as supplied differed very little from raw water, the quality being considerably below all accepted standards. Hankinisation of city supply for short period when bleach supply failed gave rise to many complaints of objectionable colored growths due to manganese bacteria. Vibrios appeared in water in July and chlorination was immediately adopted. Chlorination of filtered water was rendered ineffective by the hydrogen sulphide present, and point of application was shifted to the raw water. Notwithstanding this treatment the vibrios persisted in the water supplied to the city. It was found that the vibrios were not true *V. cholerae*. Experiments on double filtration employing bed of

coke for primary filtering medium followed by sand filtration at double the normal rate were unsuccessful.

Developing and Protecting Underground Water Supplies. J. G. Montgomery. Proceedings Ninth Texas Water Works Short School, January, 1927. pp. 125–129. (Abstract by W. M. Olson.)

Discusses protection of underground water supplies with particular reference to Texas conditions. Includes instructions developed by Layne-Texas Company to prevent pollution of new wells during construction and to provide initial disinfection upon completion. "After well has been completed and developed, six 2-ounce capsules of chloride of lime for each 100 gallons of water within the pipe should be sent to the bottom of the well. Well should not be pumped again for 48 hours."

Discussion of paper by Julian Montgomery presents data concerning supplies from the "sheet water" of West Texas. A quotation from Prof. E. W. Steel states conservative methods of protecting wells.

Detention Periods Required for Coagulation of Lake Erie Water at Cleveland. W. C. Lawrence. Sixth Annual Report of Ohio Conference on Water Purification, 1926. pp. 51–55. (Abstract by R. E. Thompson.)

Data obtained in study of retention periods required for coagulation at Cleveland plants are presented. Definite conclusions can not yet be formed as to most satisfactory detention period. While work wa carried out solely for purpose of determining proper detention periods required to obtain good filter influent, it has resulted in saving in chemicals used to the extent of $5,500 in nine months.

Report of the Special Master to the Supreme Court of the United States in the cause entitled State of Wisconsin et al. v. State of Illinois and Sanitary District of Chicago, State of Missouri. et al. 197 pages. (Abstract by Arthur P. Miller.)

In the cause entitled State of Wisconsin et al. *v.* State of Illinois and Sanitary District of Chicago, State of Missouri, et al., intervening defendants, being No. 7, Original October term, 1927, the United States Supreme Court appointed as special master Charles E. Hughes. All the parties, complainants and defendants, presented their evidence and were heard in argument in Washington between November 8, 1926, and June 3, 1927.

In the special master's report the following are given as the questions of law:

"(1) Whether the complainants present a justiciable controversy and have the requisite interest to entitle them to invoke the jurisdiction of the court; and if so,

"(2) Whether the State of Illinois had the right, as against the complainants, to divert the waters of Lake Michigan in the manner and for the purposes shown, without the consent of the United States; and, if not,

"(3) Whether Congress has the authority to control the diversion; that is, in its regulation to determine whether and to what extent the diversion should be permitted; and if so,

"(4) Whether Congress has given the permission; and, if it has not directly,

"(5) Whether the Secretary of War had authority under the act of March 3, 1899, to regulate the diversion; and if so,

"(6) Whether the permit of March 3, 1925, and its conditions, are valid; and, finally,

"(7) As to the provisions of the decree which should be entered, in the light of the determination of these questions."

Mr. Hughes's conclusions on these questions of law were as follows:

"(1) That the complainants present a justiciable controversy.

"(2) That the State of Illinois and the Sanitary District of Chicago have no authority to make or continue the diversion in question without the consent of the United States.

"(3) That Congress has power to regulate the diversion; that is, to determine whether and to what extent it should be permitted.

"(4) That Congress has not directly authorized the diversion in question.

"(5) That Congress has conferred authority upon the Secretary of War to regulate the diversion, provided he acts in reasonable relation to the purpose of his delegated authority and not arbitrarily.

"(6) That the permit of March 3, 1925, is valid and effective according to its terms, the entire control of the diversion remaining with Congress."

The master's recommendations for decree are as follows:

"In the light of these conclusions, the bill, in my opinion, should be dismissed. I think, however, that if a situation should develop in which the defendants were seeking to create or continue a withdrawal of water from Lake Michigan without the sanction of Congress or of administrative officers acting under its authority, the complainant States have such an interest as would entitle them to bring a bill to restrain such action.

"I therefore recommend that the bill be dismissed without prejudice to the right of the complainants to institute suit to prevent a diversion of water from Lake Michigan in case such diversion is made or attempted without authority of law."

The Determination of Available Chlorine in Water-sterilizing Powder (Chlorine) by Means of the Horrocks Box and Hypo Tablets. S. Elliott. *Journal of the Royal Army Medical Corps*, vol. 49, No. 2, August 1927, pp. 116–118. (Abstract by S. H. Smith.)

A method, not as accurate as laboratory methods, but sufficiently so for rough work in the field, for determining the amount of available chlorine in water-sterlizing powders, is described. The method contemplates the use of the Horrocks box, but gives capacities of cups and scoops included in such box, and gives the strength of the few solutions used. The method is simple, and it should take only a few minutes to make such a test.

The Value of Methods for the Differentiation of Bacilli of the Coli-aerogenes Group, when Applied in Shanghai. E. P. Hicks. *Journal of Hygiene*, vol. 26, No. 3, August, 1927 pp. 357–361. (Abstract by C. T. Butterfield.)

The collection made of the coli-aerogenes group included the following strains: 100 from human, 50 from animals, and 50 from soil. The tests applied were: Methyl red, Voges-Proskauer, Koser's citrate, and indol production. Before each test the respective media were incubated for five days at 37° C.

Very little difference was noted between the fecal strains from human and animal sources. With the citrate test, 92.7 per cent of the human-animal strains failed to grow, while only 20 per cent of the soil strains failed. Indol was produced by 91.3 per cent of the strains from fecal sources and by 32 per cent of those from the soil. With the methyl red and Voges-Proskauer tests, 95.3 per cent of the fecal strains and 76 per cent of the soil strains were M. R. + and V. P. –. From this the author concludes in part that the citrate and indol tests are of value, the citrate being the better of the two, and that the methyl red and Voges-Proskauer tests are of no value.

Inasmuch as the soil samples were collected chiefly from railway embankments, rifle ranges, and the tops of grave mounds, it is possible that some fecal strains may have been present in the soil.

Discussion of Raw Water Chlorination Experiments at Sandusky. L. H. Enslow, Sixth Annual Report of the Ohio Conference on Water Purification, 1926, pp. 57–59. (Abstract by R. E. Tarbett.)

Chlorine, when first applied to water or sewage, combines with the organic substances having an avidity therefor; oxidation is not obtained until this demand is satisfied and free chlorine is present to a considerable extent.

Reduction of hydrogen ion concentration and phenol distinction require that a considerable excess of free chlorine be maintained. Increased coagulation efficiency due to prechlorination is probably caused by a change brought about in the colloidal substances.

In a number of Texas plants, algal growths in reservoirs have been controlled by chlorination of the entering water. In one plant the addition of a small amount of lime following the application of chlorine was found more efficacious than chlorine alone. Bacterial aftergrowths following chlorination would appear to have little significance from standpoint of nuisance or pathogenic quality.

Superchlorination followed by dechlorination with liquid sulphur dioxide for elimination of tastes and odors from chlor-substitution products has been successful at Toronto. Contact of one hour is allowed, the residual chlorine being 0.3 to 0.6 p. p. m. at time of dechlorination. This residual is reduced to 0.1 p. p. m. Sulphur dioxide is added in same manner as liquid chlorine.

Supervision of Public Water Supplies in Connecticut. Warren J. Scott, *Connecticut Health Bulletin*, vol. 41, No. 11, November, 1927, pp. 235–239. (Abstract by H. V. Pedersen.)

This article is a brief summary of the effort the State department of health is constantly making to safeguard and improve the public water supplies of the State Some of the activities discussed are listed as follows: (1) Inspection of watersheds; (2) chlorination plant inspection; (3) filter plant inspection; (4) investigation of complaints; (5) surveys of adequacies of supplies; (6) supervision of cross connections; (7) approval of new supplies; (8) periodic testing of all public water supplies.

The author quotes from the Connecticut statutes the power invested in the health department to protect public water supplies and discusses briefly, in an interesting and instructive way, the activities of the bureau of sanitary engineering.

Sanitary Scoring of Water Supplies. Anon. *Public Works*, vol. 58, No. 10, October, 1927, pp. 386–388. (Abstract by R. J. Faust.)

The object of the score system is to list the many sanitary dangers, the several protective measures, and the desirable qualities of the water delivered. The assignment of numerical penalties and credits is for the purpose of indicating relative values in an approximately quantitative way. The committee of the New England Water Works Association, which presented the scoring system as outlined in the article, does not pretend that the values given are the best that can be selected, nor that they are exact, but it does believe that the values are relatively reasonable. An outline of the score system is included in the article.

Aeration of Water and Sewage. Anon. *Public Works*, vol. 58, No. 10, October 1927, pp. 366–367. (Abstract by R. J. Faust.)

To prove that considerable aeration takes place from the surface of the air bubbles as they ascend through a column of water, special experimental apparatus was devised. This apparatus eliminates the criticism that a bulk of the aeration comes by "streaming" from the upper surface when the bubbles break. A picture of the apparatus and an explanation of the experiment are given. The results are in tabular form and show conclusively that aeration takes place from the surface of air bubbles as they ascend through water.

Note on the Aeration of Water. Gilbert J. Fowler and S. N. Chatterjee. *The Surveyor*, vol. 72, No. 1855, August 12, 1927, p. 139. (Abstract by D. C. Ruchhoft.)

An apparatus, consisting principally of 3 aspirator bottles and an aeration chamber made of the outer jacket of a Liebig condenser, arranged to determine the amount of oxygen that is dissolved from surface streaming and from air bubbles passing through the liquid in the condenser is described. When water containing about 1.0 p. p. m. of dissolved oxygen was allowed to stand in the condenser with only a small tube open to the air the oxygen content was increased to 1.2 p. p. m. in 24 hours. When the condenser was not quite full, leaving an area of water equal to the cross section of the condenser exposed, the solution of oxygen from the streaming effect was increased to 5.0 p. p. m. after standing an additional 24 hours. However, if air was slowly bubbled through the water in the condenser for only ten minutes, the oxygen content was increased from 1.0 to 5.0 p. p. m. The authors present this experiment to controvert the opinion that probably only a very minute quantity of oxygen is absorbed by sewage as air passes through it and that most of the aeration takes place at the surface.

Historical Review of Development of Control of Disease-Bearing Mosquitoes. J. A. LePrince. Proceedings of the American Society of Civil Engineers, Part I, September, 1927, pp. 1637–1640. (Abstract by L. L. Williams.)

This is a brief outline of the history of yellow fever and malaria. Yellow fever was last seen in this country in 1905. Savannah, Georgia, was the first city to make a serious attempt at malaria reduction, when they passed a law forbidding the maintenance of wet-culture (as rice culture was then called) near the city, and reimbursed the landowners for loss of potential crops. It details the wide extent of malaria up to the eightys, and shows a gradual decrease of malaria through extension of intensive farm drainage and improved living conditions, reduction of the cost and more general use of quinine, and the provision of metallic screens for the protection of homes. The first mosquito campaign was begun by Americans in Habana in 1901, against both yellow fever and malaria. The first antimosquito campaign in the United States was in connection with control of yellow fever in New Orleans, in 1905. Campaigns against malaria and the control of the disease due to mosquitoes in the United States were started in 1913, when surveys were first made in Virginia-North Carolina by Dr. H. R. Carter, of the United States Public Health Service. The first Federal appropriation of $16,000 was made in 1914 to the Public Health Service for investigations in malaria. Additional money has been furnished, and these investigations have continued to the present time.

The author estimates that extra-cantonment malaria work prevented the loss of approximately 5,000 men by death from malaria. After the World War the United States Public Health Service cooperated with the International Health Board and the State health departments in Southern States and started malaria-control activities in fourteen States. This control work still continues. Prior to 1914, less than six communities had undertaken malaria-control measures and the results were unsatisfactory. Since 1914, malaria-control measures have been satisfactory in 343 communities and 216 counties in 17 States; and surveys, control measures, and investigations have been carried on in 667 communities in 376 counties in 24 States.

It has been the author's good fortune to take an active part in all of the campaigns, commencing at Habana, Cuba, in 1901; with Gorgas and Carter in the Canal Zone; and then back to active work in the United States. "Every indication points to a reduction in malaria throughout the United States at a rate equal to, or possibly even more rapid rate than, that which has been attained in

the past twenty-five years. Should this prove true, it needs no prophet to foretell the outcome."

Paris Green as a Larvicide. Carlos Del Negro. *Archivos De Hygiene,* Department of Health, Brazil, vol. 1, No. 2, September, 1927, pp. 143–158.

"First. In a series of experiments carried out in Campos (State of Rio, Brazil), Paris green as a larvicide was found successful over any kind of vegetation. After the third, fourth, fifth, and sixth experiments, anopheline larvae were found living only at the percentages of 3, 4, 0.8, and 3, respectively. The used batch of Paris green contained only 40 per cent of arsenious acid.

"Second. The larvicide is employed in a mixture of 1 liter to 100 liters of dirt to 10,000 square meters of marsh. It was very difficult to maintain this rate.

"Third. The larvicide had no action on the pupae.

"Fourth. It was not harmful to the other swamp inhabitants, including the culicine larvae."

DEATHS DURING WEEK ENDED FEBRUARY 4, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended February 4, 1928, and corresponding week of 1927. (From the Weekly Health Index, February 8, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended Feb. 4, 1928	Corresponding week 1927
Policies in force	70, 192, 320	66, 658, 783
Number of death claims	13, 911	13, 939
Death claims per 1,000 policies in force, annual rate	10. 4	10. 9

Deaths from all causes in certain large cities of the United States during the week ended February 4, 1928, infant mortality, annual death rate, and comparison with corresponding week of 1927. (From the Weekly Health Index, February 8, 1928, issued by the Bureau of the Census, Department of Commerce)

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Data for 36 cities.
[4] Deaths for week ended Friday, Feb. 3, 1928.
[5] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15, Louisville, 17; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32, and Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

SUMMARY OF MONTHLY REPORTS FROM STATES

The following summary of monthly State reports is published weekly and covers only those States from which reports are received during the current week:

State	Meningococcus meningitis	Diphtheria	Influenza	Malaria	Measles	Pellagra	Poliomyelitis	Scarlet fever	Smallpox	Typhoid fever
December, 1927										
Hawaii Territory	3	30	4		7		2	2	0	6
Indiana	3	216	127		178		11	421	[1] 357	24
Oregon	9	63	110		82		64	134	180	22
Virginia	3	279	2,421	45	743	13	2	287	3	34
January, 1928										
Arizona	10	60			64	2	2	24	9	7
Connecticut	2	177	23	1	606		3	496	125	5
Florida	2	67	43	22	29	1		45	19	30
Nebraska	8	40	17		37			322	161	6

[1] Corrected report.

December, 1927	Cases
Chicken pox:	
Hawaii Territory	18
Indiana	322
Oregon	249
Virginia	583
Conjunctivitis:	
Hawaii Territory	58
Dysentery:	
Virginia	41
Favus:	
Oregon	1
Hookworm disease:	
Virginia	7
Impetigo contagiosa:	
Oregon	9
Leprosy:	
Hawaii Territory	2
Lethargic encephalitis:	
Oregon	1
Mumps:	
Hawaii Territory	18
Indiana	68
Oregon	62
Paratyphoid fever:	
Hawaii Territory	2
Scabies:	
Oregon	26
Septic sore throat:	
Oregon	7
Tetanus:	
Hawaii Territory	1
Trachoma:	
Hawaii Territory	101
Trench mouth:	
Oregon	1
Whooping cough:	
Indiana	77
Oregon	18
Virginia	401
January, 1928	
Anthrax:	
Nebraska	1
Chicken pox:	
Arizona	51
Connecticut	582
Florida	172
Nebraska	274
Conjunctivitis:	
Connecticut	3
Dengue:	
Florida	2

	Cases
Dysentery:	
Florida	5
Favus:	
Connecticut	1
German measles:	
Connecticut	17
Nebraska	4
Hookworm disease:	
Florida	57
Lethargic encephalitis:	
Connecticut	3
Mumps:	
Arizona	17
Connecticut	390
Florida	19
Nebraska	125
Paratyphoid fever:	
Connecticut	3

	Cases
Rabies in animals:	
Connecticut	3
Rabies in man:	
Arizona	1
Septic sore throat:	
Connecticut	12
Nebraska	9
Tetanus:	
Connecticut	2
Florida	8
Trachoma:	
Arizona	10
Typhus fever:	
Florida	2
Whooping cough:	
Arizona	24
Connecticut	516
Florida	6
Nebraska	47

Number of cases of certain communicable diseases reported for the month of November, 1927, by State health officers

State	Chicken pox	Diphtheria	Measles	Mumps	Scarlet fever	Smallpox	Tuberculosis	Typhoid fever	Whooping cough
Alabama	81	434	75	33	138	28	300	100	77

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 96 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 30,890,000. The estimated population of the 91 cities reporting deaths is about 30,230,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended January 28, 1928, and January 29, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
43 States	2,182	2,001	
96 cities	1,147	1,049	1,063
Measles:			
42 States	12,410	9,972	
96 cities	3,398	2,524	
Poliomyelitis:

City reports for week ended January 28, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

[2] Typhus fever: 1 case at Houston, Tex.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended January 28, 1928, compared with those for a like period ended January 29, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, December 25, 1927, to January 28, 1928—Annual rates per 100,000 population, compared with rates for the corresponding period of 1926–27 [1]

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended January 14, 1928.—The following report for the week ended January 14, 1928, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt.—Suez.
Aden Protectorate.—Aden.
India.—Bombay, Rangoon, Moulmein.
Ceylon.—Colombo.
Dutch East Indies.—Makassar.

CHOLERA

India.—Bombay, Calcutta, Rangoon.
Straits Settlements.—Singapore.

CHOLERA—continued

Siam.—Bangkok.
French Indo-China.—Saigon-Cholon.

SMALLPOX

India.—Bombay, Negapatan, Madras, Calcutta, Rangoon, Moulmein.
French Indo-China.—Saigon-Cholon.
Dutch East Indies.—Belawan-Deli.
Sarawak.—Kuching.
China.—Hong Kong.

Returns for the week ended January 14 were not received from the following ports:

India.—Tuticorin, Vizagapatam, Bassein.
Dutch East Indies.—Pontianak.
China.—Canton.
Union of Socialist Soviet Republics.—Vladivostok.

ARGENTINA

Buenos Aires—Plague.—A death from plague was reported at Buenos Aires, Argentina, February 9, 1928. Unconfirmed newspaper reports announced four other deaths from plague in Buenos Aires.

Rosario—Plague—January 15–25, 1928.—According to information dated February 6, 1928, four cases of plague were reported at Rosario, Argentina, during the period January 15 to 25, 1928. The president of the Department of Hygiene of Argentina states that the work of destroying rats by poison, traps, and other measures is going on continuously at Rosario, that ships are being protected against rats, and that the spread of the disease is not anticipated. Similar measures are being taken at other ports in Argentina.

BAHAMA ISLANDS

Measles—Typhoid fever—March 1, 1927–January 28, 1928.—Information received under date of January 28, 1928, shows the occurrence of 86 cases of measles and 112 cases of typhoid fever with six deaths in the Bahama Islands during the period March 1, 1927, to January 28, 1928.

BOLIVIA

Water supply systems—Municipalities.—Information received under date of July 29, 1927, shows that the cities of Cochabamba, La Paz, Oruro, Potosi, Sucre, Santa Cruz, and Trinidad, Republic of Bolivia, have municipal water-supply systems, but that no system of filtration or purification of water exists in any of these localities. La Paz, Oruro, and Cochabamba are stated to have concrete sewers which are separate from the storm water drainage system. The other cities have only old subterranean canals of rubble masonry. Oruro receives its supply from the springs of Calacala; Cochabamba from Artesian wells; Potosi from reservoirs constructed in the Kari-kari mountains; Sucre from the waters of the Cajamarca River. It was stated that the water supply of La Paz was not free from mineral and organic impurities. The present water supply of La Paz was stated to be little in excess of 12 liters per day per capita, whereas it should be about 1,000 liters per day per capita.

BRAZIL

Pernambuco, Natal, Parahyba, Fortaleza—Health conditions—Vital Statistics, 1922–1926.—Health conditions in the cities named are said to be generally good, but the rural districts and smaller interior cities are more backward.

Yellow fever is said not to be a matter of great concern to Brazilians and, as at present controlled, not a grave menace to foreigners.

In 1925 and 1926 an epidemic of smallpox occurred in Pernambuco which affected neighboring States.

In 1926 two cases of bubonic plague occurred in Triumpho, Pernambuco, but the disease did not spread. A plague prevention post was established at Triumpho in 1927.

Some cases of typhoid fever and numerous cases of influenza are usually present in the State of Pernambuco. "Grippe intestinal" and dysentery are the diseases most often reported in the States of Rio Grande do Norte, Parahyba do Norte, and Ceara. Tuberculosis and malaria are said to be the chief causes of death in the States named.

Among the middle and upper classes hygienic and sanitary conditions are said to be good. The houses, as a rule, are kept clean. The storing of water in earthenware receptacles is a common practice, and flies are numerous.

American residents in this part of Brazil ordinarily observe sanitary precautions, drink boiled water or mineral water, avoid the use of raw vegetables, and take frequent vacations to minimize the effects of the tropical climate.

The following table gives vital statistics for the cities named for the years 1922 to 1926, inclusive:

CITY OF RECIFE (PERNAMBUCO)

	1922	1923	1924	1925	1926
Population	270,000	320,000	330,000	355,871	361,553

Yellow fever	Nil.	Nil.	Nil.	2	17

CITY OF FORTALEZA (CEARA)

	1922	1923	1924	1925	1926
Population	90,000	90,000	90,000	95,000	100,000
Births (living infants)	1,461	818	858	863	894
Births (stillborn)	62	55	49	76	79
Deaths	2,318	2,300	2,795	2,076	2,639
Death rate per thousand	25.75	25.55	31.05	21.85	26.39
Deaths under 2 years of age	865	853	1,162	759	1,104

Rio de Janeiro—Plague.—Two cases of plague were reported in Rio de Janeiro, Brazil, recently. The first case occurred January 17, 1928. A plague-infected rat was reported January 16, 1928, in Rio de Janeiro.

CANADA

Provinces—Communicable diseases—Week ended January 28, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended January 28, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever			1	1		1		3
Influenza	4			12	2	1		19
Lethargic encephalitis					1			1
Smallpox				77	1	15	19	112
Typhoid fever	4	7	19	11	1		3	45

Quebec—Communicable diseases—Week ended January 28, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended January 28, 1928, as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	1	Scarlet fever	94
Chicken pox	32	Smallpox	18
Diphtheria	64	Tuberculosis	32
German measles	2	Typhoid fever	19
Influenza	1	Whooping cough	33
Measles	86		

COSTA RICA

Antituberculosis and venereal disease work.—Information received under date of October 28, 1927, shows that a campaign of cure and prevention of tuberculosis and venereal diseases has been ordered to be instituted in the principal cities of Costa Rica. The campaign against tuberculosis is to be carried out mainly through visiting nurses and dispensaries are to be instituted for the free treatment of venereal diseases in the larger cities and free service by municipal doctors is to be provided in the smaller communities.

Campaign for extermination of rats—Limon and Puntarenas.—Information under date of December 16, 1927, shows that a campaign of rat extermination has been ordered into effect at Limon and Puntarenas, Costa Rico, as the result of action taken at the Pan American sanitary conference held during the autumn of 1927 at Lima, Peru.

EGYPT

Plague—December 29, 1927-January 8, 1928—Alexandria.—A fatal case of plague was reported December 29, 1927. The case occurred in an Egyptian workman employed in a cotton depot, who was found dead in his lodging, 850 meters from the port. *Suez.*—On January 8, 1928, a fatal case occurred in a native found dead in his lodging. The focus of this case was stated to be in the vicinity of a Government primary school 3½ kilometers from the port.

Summary and comparison with year 1926.—During the year ended December 31, 1927, 79 cases of plague were reported in Egypt, as compared with 150 cases reported during the corresponding period of the year 1926.

GUATEMALA

Sanitation along railway lines.—According to information received under date of November 29, 1927, sanitary work in towns on the railway connecting Guatemala City with Puerto Barrios, Guatemala, was done in October, 1927. The measures taken included oiling of stagnant water along the railway lines.

HONDURAS

Tegucigalpa—Malaria.—Cases of malaria apparently of local origin were reported at Tegucigalpa, Honduras, during the month of September, 1927. A survey showed mosquitoes breeding in two localities along the Choluteca River banks within the city limits. It was stated that measures were being applied to correct these conditions.

JAPAN

Dysentery—Tokyo, city and prefecture—November 27–December 31, 1927.—During the period November 27 to December 31, 1927, dysentery was reported in Tokyo, Japan, as follows: Tokyo City, cases, 110; deaths, 50; Tokyo prefecture, outside of the city, cases, 144; deaths, 70.

LATVIA

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported in the Republic of Latvia as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	6	Puerperal fever	5
Diphtheria	28	Relapsing fever	2
Erysipelas	8	Scarlet fever	155
Influenza	22	Tetanus	1
Malaria	3	Trachoma	16
Measles	217	Typhoid fever	87
Mumps	7	Whooping cough	15

Population, 1,950,000.

MEXICO

Manzanillo—Death from smallpox—General vaccination ordered—January 19, 1928.—Information received under date of January 19, 1928, shows that, following the occurrence of a death from smallpox during the week ended January 15, 1928, at Manzanillo, Mexico, the port medical authority has directed all local physicians at Manzanillo to assign one hour daily to the free vaccination of residents of Manzanillo, who are required to present certificates of vaccination to the medical authority.

PANAMA

Aguadulce, Province of Cocle—Antimalaria measures.—Information dated November 12, 1927, shows antimalaria work being conducted at Aguadulce, Republic of Panama. The work undertaken included control of water supply and sewerage and drainage systems.

PERU

La Oroya—Influenza and pneumonia mortality—October-December, 1927.—During the three months ended December 31, 1927, epidemic influenza in mild form was reported present at La Oroya, Peru. Many deaths from pneumonia occurred. Smallpox was said to be prevalent.

UNION OF SOUTH AFRICA

Typhus fever—December 18-24, 1927.—During the week ended December 24, 1927, fresh outbreaks of typhus fever were reported in the Cape Province, in two districts and five localities, and in Natal in one district.

During the same period, two cases of typhus fever were reported at Durban, Natal, in a European and an Asiatic. The cases were stated to be sporadic.

YUGOSLAVIA

Communicable diseases—December, 1927.—During the month of December, 1927, communicable diseases were reported in Yugoslavia as follows:

Disease	Cases	Deaths	Disease	Cases	Deaths
Anthrax	36	1	Poliomyelitis	2	
Cerebrospinal meningitis	9	4	Scarlet fever	1,691	244
Diphtheria	303	51	Tetanus	11	7
Dysentery	49	5	Typhoid fever	466	69
Leprosy		1	Typhus fever	1	
Measles	3,301	18			

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

Asst Surg Gen R. C WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests

PUBLIC HEALTH REPORTS

VOL. 43 FEBRUARY 24, 1928 NO. 8

PREVALENCE OF INFLUENZA, JANUARY 1 TO FEBRUARY 4, 1928

Preliminary reports from the health officers of 31 States for the first five weeks of 1928 indicate that the prevalence of influenza was about the same as it was during the same period of 1927, and about half that for 1926. The figures are as follows:

Cases of influenza reported by 31 States (population about 66,500,000) for the first five weeks of 1926, 1927 and 1928

Week ended—	Corresponding weeks—		
	1928	1927	1926
Jan. 7, 1928	1,230	1,120	1,663
Jan. 14, 1928	1,456	1,657	2,274
Jan. 21, 1928	1,651	1,594	3,114
Jan. 28, 1928	1,546	1,767	4,703
Feb. 4, 1928	1,869	1,560	4,942
Total	7,752	7,698	16,696

In 1926 and 1927 the peak of the influenza curve was reached early in March.

Comparable figures for the year 1925 are not available for some of the States, but the prevalence of influenza during the first five weeks of the year was greater in 1925 than it was in 1926, although in 1925 the peak of the influenza curve was reached about the middle of February and the total number of cases reported for January, February, and March was lower than it was in 1926.

The combined influenza and pneumonia death rates per 100,000 population in 94 large cities of the United States for the first five weeks of the years 1926, 1927, and 1928 were as follows:

	Death rate
1926	233
1927	198
1928	192

TRACHOMA IN THE STATE'S HEALTH PROGRAM[1]

By Paul D. Mossman, *Surgeon, United States Public Health Service*

The organized trachoma prevention work of the United States Public Health Service, in cooperation with States, began with the extensive survey made in eastern Kentucky in 1912 by Senior Surg.

[1] Read before the Public Health Section of the Southern Medical Association, Memphis, Tenn., Nov. 16, 1927.

John McMullen. This survey, made in response to a request from the Kentucky State Health Department, showed that trachoma was extremely prevalent and confirmed the statements of Dr. J. A. Stuckey and others that trachoma constituted a major public health problem in eastern Kentucky. The scope of Doctor McMullen's survey was enlarged in 1913 and 1914 to the extent of covering some 23 counties and involving the examination of over 18,000 people. On the basis of these examinations Doctor McMullen estimated that in the 35 mountain counties of Kentucky there were about 33,000 cases of trachoma. Being charged with the task of preventing the spread of trachoma, he evolved a plan which has not only stood the test of time, but has won the approval and praise of public health workers in many countries. The plan included the establishment of small hospitals which should serve not only as dispensaries and clinic centers, but as centers for field work in the form of surveys, field clinics, and educational work. The first hospitals were established in September, 1913, in Kentucky. In 1914, one was established in Virginia, following surveys by Senior Surg. Taliaferro Clark, of the United States Public Health Service, which showed that trachoma was quite prevalent in the western section of that State. Then the work spread to West Virginia, Tennessee, and, later, to Arkansas and Missouri, as the work became known and studies showed the prevalence of the disease in those States. Evidence which has accumulated as the work has progressed indicates that Missouri and Arkansas probably have as much trachoma as Kentucky had when the work began, and that it exists to a dangerous extent in several other States. It is not uniformly prevalent throughout any State; some communities are heavily infected while others are relatively or completely free from it.

At present, hospitals are being conducted in Kentucky, Tennessee, Arkansas, and Missouri, with the financial and moral cooperation of those States. The trachoma situation in Missouri began to attract attention through the action of the blind pension law which became effective in 1922, providing $300 per year for blind persons without other means of support. It was found that over 20 per cent of these pensioners were blind as a result of trachoma. This made blindness due to trachoma cost the taxpayers of the State over $200,000 annually in pensions alone, to say nothing of the economic cost in medical treatment, and the loss due to the withdrawal of these disabled persons from productive toil. Although new applicants have been added to the pension list and all the pensioners have been reexamined by very competent ophthalmologists, the percentage of cases of blindness due to trachoma has changed very little and has never dropped below 20 per cent. The latest figures (July 7, 1927) show a total of 3,152 pensioners, and of these, 637, or 20.2 per cent,

were blind from trachoma, costing the State in pensions $191,100 each year. These pensioners are completely blind, having no better vision than mere light perception. Many more have enough vision to be excluded from the provisions of this law, but not enough to enable them to earn a livelihood. Damage to vision sufficient to prevent education or the learning of a skilled trade is sufficient to depress the economic and social status of the individual and often of the family. Trachoma is thus a link in the vicious cycle of ignorance, poverty, and disease, each at once the result and the cause of the others.

The influence of the trachoma work on community interest in public health may be illustrated by the fact that Knott County, Ky., where our first hospital was located, was years ahead of many richer counties in installing a county health department. It is generally admitted that the value of public health work in that county was first shown to the people of the county by the teaching given by the hospital staff, both at the hospital and in the field. One of the first sanitary privies in the county was the one built at the hospital.

In many other localities the trachoma work has given the people their first view of public-health work of any sort and their first idea of the possibility of disease prevention. It is easier for State health authorities to persuade a county to install a full-time health department if energetic trachoma work has been done in that county. Conversely, it is possible for us to do much more effective trachoma-prevention work when we have the assistance of a well-organized county health department, especially when the State health department is manifesting an active interest in the campaign.

In introducing a specialized method of combating a single disease, the Public Health Service has not detracted in any way from the effectiveness of the regular health agencies within the State. We have utilized the services of State and county health authorities in carrying out our field work and in return they have had the services of our organization trained especially for the work, but with a public health vision broad enough to see the whole health program with trachoma prevention a component part, contributing to the success of the whole in proportion to its effectiveness in its own field.

The trachoma hospitals have a fourfold function, as follows:

1. Clinical treatment of trachoma for the purpose of preventing damage to sight and of stopping the patient from being a spreader of the disease. Field surveys have shown that the results of treatment have been good in a large majority of cases, the patients having remained free from evidence of the disease for a number of years. It has also been shown by the resurvey in Knott County, Ky., by Doctor McMullen, of the Public Health Service, and Doctor Duke, county health officer, and by field studies in several other localities,

that an intensive trachoma campaign can rid a community of the disease.

2. Study of the disease itself. We are constantly on the alert for improved methods of diagnosis and treatment. Although nothing revolutionary has been discovered, we believe that we have made substantial improvements both in accuracy of diagnosis and in effectiveness of treatment. In connection with our work at Rolla, Mo., the service is maintaining a research laboratory for the study of the etiology of trachoma from a bacteriologic standpoint. We also have an officer making an extended epidemiological study of the disease.

3. Education of patients in personal hygiene and disease prevention. Patients admitted to these hospitals receive careful treatment for trachoma and also instruction in personal hygiene, health, habits and general health education. They are enabled to go home relieved of their disease and trained to some extent at least to live in a clean, health-promoting manner.

4. Centers for field work. Trachoma surveys are made in the surrounding territory by the staffs of the hospitals, by means of examination of school children, and by community clinics. In the course of these surveys and clinics, talks are given on general health topics as well as on trachoma in particular. The chief value of the clinic, so far as trachoma is concerned, is the contact with the patient himself—establishing the diagnosis and showing him the value and importance of early treatment as well as the danger of spreading the disease to others.

During the past four months we have had a public health nurse on duty in Texas County, Mo., engaged in special field work. She was provided with a list of the Texas County residents who had been treated at the hospital. Her task was to look them up and report on their condition and also as to their home surroundings, diet, and other factors that might have a bearing on the incidence or spread of the disease. She also discovered suspicious eye trouble in other members of these households and in other homes in the community. These people were persuaded to come to the clinics which were held at Houston, the county seat, every Saturday. The clinics were conducted by a medical officer from the Public Health Service headquarters at Rolla, and the diagnosis of the cases sent in by the nurse was thus verified. Seventeen such clinics were held, with an average attendance of 95. Some patients came repeatedly for treatment or observation. The nurse made careful records of 254 persons during the summer. Of these, 230 were new patients who had never been in our hospital, and most of them had had no systematic treatment at all. As a result of this work a popular demand for a county nurse has arisen, and the county court will undoubtedly decide to

appoint a full-time county nurse half of whose salary will be paid by the State health department, and it is not too much to hope that another season's work may help in getting a full-time health officer for the county.

We have a somewhat similar study now going on in eastern Tennessee, which will require many months to complete, but which has already shown that in certain counties trachoma is apparently about to become a thing of the past as a result of the work done in that part of the State during the past 11 years.

No one realizes better than those of us who are in the work how far from perfect it is both in organization and execution. The chronicity of the disease, the time required to arrest it, the lack of hospitals large enough to be conducted economically, the ignorance of the people, the sad home conditions they return to when they leave the hospital—these and many other conditions make up the list of problems we must continually face. The work does have an appeal to the public, however, and legislators are not immune to this appeal when they are made acquainted with the prevalence of the disease in their State and the effectiveness of the cooperative campaign of the State health department and the United States Public Health Service.

AN EPIDEMIOLOGICAL AND STATISTICAL STUDY OF TONSILLITIS, INCLUDING RELATED THROAT CONDITIONS

In view of the widespread attention which has been given in recent years to tonsil defects and their remedy by tonsillectomy, it was deemed worth while for the Public Health Service to make a study of acute and chronic diseases of the tonsils and throat. Public Health Bulletin No. 175, by Selwyn D. Collins, associate statistician, United States Public Health Service, gives the results of this study.[1]

The data used consist of (*a*) records of sickness occurring in several groups of people kept under observation for illness for several years, and (*b*) results of physical examinations made by medical officers of the United States Public Health Service in the course of various field studies conducted during the past 10 years. The bulletin considers acute tonsillitis and sore throat, enlarged and diseased tonsils as found on physical examination, and the relation of the condition of the tonsils to illness and to physical defects. Mortality from diseases of the tonsils and pharynx is also briefly considered.

Some of the outstanding results are summarized below:

The incidence of tonsillitis and related conditions of the pharynx is higher among children of school ages than before or after those ages.

[1] This bulletin may be purchased through the Superintendent of Documents, Government Printing Office, Washington, D. C., at 30 cents per copy.

Laryngitis, on the other hand, appears to occur more frequently among adults than among preschool or school children. Tonsillitis and related conditions of the pharynx appear to be the only important respiratory affection which shows this particular age incidence; that is, higher during the school ages than among younger or older persons.

The incidence of tonsillitis and related conditions of the pharynx appears to be considerably higher for females than for males.

The relative age incidence of acute tonsillitis and sore throat is strikingly similar to the relative age prevalence of diseased tonsils as found on physical examination. The relative prevalence of enlarged tonsils as found on physical examination is also similar to the relative age incidence of acute tonsillitis and sore throat, but does not show as close correspondence as the curve for diseased tonsils.

The prevalence of defective tonsils does not seem to be significantly greater in rural than in urban districts. The percentage having had the tonsils removed, however, was considerably larger in the urban groups examined than in the rural.

The prevalence of defective tonsils seems to vary somewhat with the season of the year, but the variation is less than is the variation in the incidence of acute tonsillitis and sore throat. The maximum prevalence of defective tonsils appears to be reached about April, a period of two or three months after the maximum incidence of acute tonsillitis and sore throat and of colds.

The incidence of sore throat seems to be more than twice as great for school children with defective tonsils as for those whose tonsils have been removed. The incidence of sore throat among children with normal tonsils also appears to be less than among those with defective tonsils.

Respiratory diseases other than tonsillitis appear to be somewhat more frequent among children with defective tonsils than among those with normal tonsils or those whose tonsils have been removed. Among adults there seems to be little difference in the incidence of these respiratory diseases in the different tonsil groups.

The incidence of illness from rheumatism and related conditions appears to be higher among adults who have attacks of tonsillitis than among those who are free from tonsillitis.

The incidence of diphtheria seems to be much higher among children with defective tonsils than among children with tonsils removed. Among children with normal tonsils it appears to be only slightly higher than among those whose tonsils have been removed.

The results of the physical examination suggest that adenoids, enlarged cervical glands, conjunctivitis, eyestrain, and decayed teeth

all tend to be slightly more prevalent among children with defective tonsils than among children with normal tonsils or with tonsils removed.

Filled teeth are more prevalent among children with tonsils removed, indicating that these children are a somewhat selected group, coming from families that are more able or willing to secure the correction of other remediable physical defects in their children.

Height and weight measurements and records of growth in weight over a period of nine months for a group of school children did not show any advantage in the growth of one tonsil group over another. Data from the literature seem to indicate a more rapid growth immediately .tonsillectomy, but this tendency does not appear to continue for any extended period of time.

DEATH RATES IN A GROUP OF INSURED PERSONS

RATES FOR PRINCIPAL CAUSES OF DEATH FOR DECEMBER, 1927, AND FOR THE YEARS 1911, AND 1917 TO 1927

The accompanying tables are taken from the Statistical Bulletin for January, 1928, issued by the Metropolitan Life Insurance Co. They present the mortality experience of the industrial insurance department of the company for the principal causes of death for December, 1927, and a comparison of the rates for the years 1911 and 1917 to 1927, inclusive. The rates are based on a strength of approximately 18,000,000 insured persons of the United States and Canada. In recent years the death rates in this group have been about 72 per cent of the rates for the death registration area of the United States.

DECEMBER, 1927

The month of December, 1927, as was the case with five other months of the year, registered a lower death rate than had ever before been recorded for the corresponding month of any year. The death rate for December was 8.7 per 1,000, as compared with the previous low rate of 8.9 for December, 1925.

While the rate for almost every cause of death listed in the accompanying table is lower than that registered last year, the most important single factor in the low December death rate is stated to be the low mortality, for a winter month, from pneumonia. Other noteworthy reductions were those for tuberculosis, cancer, and Bright's disease.

There were more automobile fatalities than in December, 1926, and this was the tenth month of the year 1927 to record an increase in such deaths over the corresponding month of last year.

Death rates (annual basis) for principal causes per 100,000 lives exposed, December, 1927, as compared with November, 1927, and December and year 1926

[Industrial department, Metropolitan Life Insurance Co.]

Cause of death	Rate per 100,000 lives exposed [1]			
	Dec., 1927	Nov., 1927	Dec., 1926	Year 1926
Total, all causes	866.0	849.8	932.5	945.6
Typhoid fever	2.8	4.3	4.1	4.2
Measles	2.0	1.0	3.3	10.2
Scarlet fever	2.5	2.6	2.4	3.4
Whooping cough	3.7	3.9	5.8	9.6
Diphtheria	14.3	12.4	15.5	9.7
Influenza	17.7	11.0	18.7	31.1
Tuberculosis (all forms)	84.0	79.2	89.7	99.0
Tuberculosis of respiratory system	74.1	70.3	80.1	86.7
Cancer	73.0	73.5	78.4	73.7
Diabetes mellitus	18.1	16.2	20.2	16.7
Cerebral hemorrhage	56.0	53.2	54.7	55.6
Organic diseases of heart	135.3	133.2	139.7	134.3
Pneumonia (all forms)	83.5	66.0	97.4	98.2
Other respiratory diseases	16.4	14.9	15.2	13.0
Diarrhea and enteritis	16.1	23.1	17.4	29.8
Bright's disease (chronic nephritis)	65.7	66.7	78.0	73.5
Puerperal state	12.3	14.5	12.8	15.3
Suicides	7.2	8.0	7.4	7.7
Homicides	6.6	7.6	7.3	7.0
Other external causes (excluding suicides and homicides)	59.9	62.4	62.2	62.3
Traumatism by automobiles	16.5	20.8	14.3	16.8
All other causes	180.0	194.2	202.3	191.0

[1] All figures include infants insured under 1 year of age.

YEAR 1927 AND COMPARISON WITH 1911 AND YEARS 1917 TO 1926

In 1927 a new low minimum death rate of 8.4 per 1,000 was established for this group of persons, which comprises one-seventh of the total and more than one-fourth of the urban populations of the United States and Canada. This favorable health condition probably obtained in, and will no doubt be reflected in the death rates for, the registration area. The previous low rate for this group was 8.5 per 1,000 for the years 1924 and 1925, and the next lowest was 8.9 in 1926. The importance of these fractional reductions is much more obvious when they are translated into figures showing the actual savings of lives. If the 1926 death rate had prevailed in 1927 there would have been 8,808 more deaths than actually occurred in the group of persons here considered, and the reduction of one-tenth of one point from the 1925 death rate represents 1,782 fewer deaths.

A new low death rate was recorded for tuberculosis, 93.5 per 100,000. This may be compared with the previous minimum rate of 98.2 in 1925, with 137.9 in 1920, with 189.0 in 1918, and with 224.6 in 1911. Improved conditions as compared with 1926 were shown also for measles, scarlet fever, whooping cough, pneumonia, influenza, diarrhea and enteritis, and the principal degenerative diseases.

On the other hand, the cancer rate was slightly higher, the diabetes rate and the rate for puerperal diseases were the same as in 1926, and the rate for automobile fatalities rose from 17 to 18.6, an increase

of 9.4 per cent over the preceding year. The 1927 figure for automobile fatalities is almost twice that for 1917, more than three times the rate for 1915, and more than eight times the rate for 1911.

Death rates for principal causes per 100,000 lives exposed, 1911 and 1917 to 1927, ages 1 and over

[Industrial department, Metropolitan Life Insurance Co.]

Cause of death	1927	1926	1925	1924	1923	1922	1921	1920	1919	1918	1917	1911

NATIONAL NEGRO HEALTH WEEK TO BE OBSERVED APRIL 1 TO 8, 1928

The week of April 1 to April 8, 1928, has been set aside for the fourteenth observance of National Negro Health Week. State and municipal health departments, voluntary health organizations, and numerous other official and unofficial agencies interested in race welfare and advancement are cooperating with the United States Public Health Service in a determined effort to improve health and living conditions.

As a first step in this widespread health campaign this year the Public Health Service announces the issuance of the annual National

Negro Health Week Bulletin. This publication outlines effective methods of instituting and successfully carrying out the program of the health week. It is designed primarily for churches, schools, fraternal organizations, welfare societies, and other groups interested in community progress and race betterment, and contains, in addition to methods for organizing the programs for health week, information and sources of materials of value for health-week work.

It is the plan of the campaign to set aside each day of the week for special observance of some phase of health work. Sunday, April 1, will be mobilization day; Monday, April 2, home hygiene day; Tuesday, April 3, community sanitation day; Wednesday, April 4, children's health day; Thursday, April 5, adult's health day; Friday, April 6, special campaign day; Saturday, April 7, general clean-up day; Sunday, April 8, report and follow-up day.

In addition to the bulletin there is being distributed this year a specially prepared poster which gives in brief and interesting form the various rules of health and appropriate information and which has for a number of years contributed to the success of National Negro Health Week. This poster is a beautifully printed three-color illustration, and it is the aim of the committee in charge of this activity to have a copy placed in every home.

The poster is being issued in a very limited edition for free distribution. Single copies or quantities of the poster or bulletin may be purchased at nominal cost from the Superintendent of Documents, Government Printing Office, Washington, D. C.

Health officials, race leaders, and others interested in the successful promotion of this health-week observance can secure sample copies of the bulletin or additional information as to the proposed plan of the health week by writing the United States Public Health Service, Washington, D. C., or the National Negro Health Week Committee, Tuskegee, Ala.

CLAIM AGAINST CITY BECAUSE OF ILLNESS FROM TYPHOID FEVER

The following item regarding a claim against a municipality on account of the contraction of typhoid fever, alleged to have been due to the city's negligence, is taken from the February 6, 1928, issue of the Health News, published by the New York State Department of Health:

The father of a girl who contracted typhoid fever during an outbreak of the disease in the city of Cohoes last October has filed with the comptroller and the commissioner of public works of that city a claim of $5,000 for damages and $1,000 for expenses of the sickness and the loss of his daughter's services. If the claims are not allowed by the city within three weeks, papers are ready for starting action in the supreme court, according to the Cohoes American.

It is alleged that the girl contracted typhoid fever as a result of drinking water coming from the city main into her home. The city is called grossly negligent in permitting polluted water from the canal to enter the city mains at an industrial plant through a cross connection which it is claimed has existed since July 1, 1926, in violation of regulation 15-a of Chapter VII of the Sanitary Code.

On September 18 water was shut off from the mains in that section of the city and the plant in question is said to have then pumped water from the canal to maintain pressure in its sprinkler system. It is alleged that the polluted water was forced through the cross connection into the city mains, mingling with the city water when the latter was turned on. There were 48 cases of typhoid fever reported from the general vicinity of this cross connection.

COURT DECISION RELATING TO PUBLIC HEALTH

Garbage ordinance held reasonable.—(Washington Supreme Court; State (city of Auburn) *v.* Spiller, 262 P. 128; decided December 21, 1927.) An ordinance of the city of Auburn, which required the maintenance and use of a metal garbage can by householders and operators of business places, also contained the following provision:

> * * * that in any prosecution for the violation of any provision of this section it shall be competent to prove that the person failing to furnish and provide or maintain such metallic can or deposit garbage therein as in this section provided is purchasing water from the city of Auburn for use upon such premises, and proof of such purchase of water shall be prima facie evidence that garbage is accumulating upon such premises.

This provision was attacked and the supreme court, after citing cases sustaining the validity of a legislative presumption of one fact from evidence of another, decided that there was in the instant case a rational connection between the fact proved and the ultimate fact presumed, saying:

> * * * The lawmaking body evidently reasoned that the purchasing of water from the city by a person in possession or in charge of premises located therein for use on such premises must of necessity be using them in such a manner as to accumulate garbage. While the reasoning may be somewhat attenuated, we can not conclude that it is without foundation. There are uses, of course, to which the water could be put which would not result in the accumulation of garbage, but such uses are occasional rather than general The more common use of water by persons residing in municipalities is for household purposes, and to conduct a household of necessity results in the accumulation of garbage. In this connection it may be well again to call attention to the fact that the presumption to which the ordinance gives rise is not conclusive. It is a prima facie presumption only, and does not shut out from a party affected the right to show that the actual fact is otherwise.

The court also stated that "we find nothing unreasonable in the regulations of the ordinance now before us."

PUBLIC HEALTH ENGINEERING ABSTRACTS

United States District Court Upholds Minneapolis Zoning Ordinance. Anon. *Engineering News-Record*, vol. 99, No. 13, September 29, 1927, p. 525. (Abstract by E. G. White.)

The Federal District Court of Minnesota, on September 8, 1927, rendered two decisions upholding the Minneapolis zoning ordinance. Four instances are cited where zoning ordinances were upheld by the United States Supreme Court, at Euclid, Ohio, November, 1926; Minneapolis, March, 1927; Roanoke, Va., May, 1927; and Los Angeles, June, 1927.

The case decided by the Federal District Court on September 8 involved an attempt to compel the city of Minneapolis to allow the use of property for industrial purposes which had been zoned for multiple family residences. The property had once been zoned for industrial purposes, but at the request of the board of regents of the University of Minnesota had been rezoned as dwelling property to protect the university neighborhood from industrial encroachment. Judge John B. Sanborn, who rendered the decision, expressed an opinion to the effect that the theory of zoning ordinances is good, but may be unjustly applied in some cases. He was not of the opinion, however, that judges of the Federal court could remedy matters by substituting their judgment for that of the legislative bodies.

Cities of the United States with Zoning Ordinances Totaled 553 on July 1. Anon. *Engineering News-Record*, vol. 99, No. 13, September 29, 1927, p. 526. (Abstract by E. G. White.)

According to a report issued by the United States Department of Commerce on July 1, 1927, a total of 553 cities in the United States had adopted zoning ordinances. New York was the first, in 1916, and the other cities range in size down to places with less than 1,000 population. New York State heads the list, having 93 cities, while 8 States have only one city each with zoning ordinances. In all, 46 States and the District of Columbia permit at least some municipalities to zone themselves, and of these 28 follow largely the "standard State zoning enabling act" issued by the Department of Commerce first in 1924.

The Maintenance of Satisfactory Air Temperatures in Living Spaces and Working Spaces in Ships of the British Navy. T. B. Shaw. Journal of State Medicine, vol. 35, No. 10, October, 1927, pp. 575-590. (Abstract by Leonard Greenburg.)

Captain Shaw emphasizes the fact that the ill effects of poorly ventilated quarters are due to physical and not to chemical changes in the atmosphere. Ventilation, he says, implies not only adequate air renewal but also the maintenance of the air in a satisfactory condition of temperature, moisture, and movement, and of these three conditions temperature is the most important.

From the point of view of the Navy the following questions require consideration: (1) Wild heat and methods for its control; (2) excessive heating in the Tropics and subtropical seas and its control; (3) heating arrangements in cold weather.

Wild heat is that heat which is generated in the boiler or engine rooms of the ship and is transmitted from these and hot pipes in the ship through the metal structures and into the living quarters on board. Much can be done in the limitation of this when the ships are under construction by the use of nonconducting lagging materials wherever this heat may be released. In addition, the supply of fresh, cool air by fan systems, as well as the removal of warm air by exhaust systems, is indicated, and finally the selection of suitable sites for sources of wild heat, such as dynamo and auxiliary engine rooms, is to be advocated. Such living spaces which are materially overheated may be rendered more livable by the rapid renewal of outdoor air, which is insured by a satisfactory method of plenum ventilation.

In tropical climates the problem of heat control on board ships becomes a still more difficult matter; for here, in addition to the heat generated within the ship, the direct action of the sun's rays on the ship's framework and the

warm state of the atmosphere add their quota to the temperature on board, and, moreover, the outdoor air is oftentimes not cool enough to serve as a cooling agent for use by exhaust fans. Under these conditions the sources of wild heat must be carefully examined and efforts made to reduce the transmission of heat in every possible manner. The regulation of the use of steam and the use of hot water for bathing at certain stated periods in the morning and afternoon may aid in the temperature control of certain portions of the ship; and finally the necessity for a generous supply of table fans to secure wide air motion is advocated.

Measures should be taken to diminish in so far as possible the heat absorption by the decks and the sides of the ship. This heat may be controlled by the use of white paint, awnings, and nonconducting materials. Sleeping on deck should be encouraged, not only because the open air insures greater comfort but also because of the relief from overcrowding the spaces below deck.

The part played by clothing is exceedingly important, and men working in spaces between decks in the Tropics should remove their jumpers in order that the heat loss from the body may be increased. In temperate climates, also, this procedure may be utilized to advantage.

The possibility of cooling air for use between decks is discussed, and in this connection the author points out that in temperate climates magazine cooling and that required for cold storage constitute a severe drain on the refrigerating apparatus on board ship. Apparatus must, however, be installed for cooling air in any compartment occupied by men in which the temperature will rise to an extent which will endanger life. For certain workshops situated in close proximity to wild heat which can not be effectively combated it is essential to supply cool air.

In H. M. ships the methods of heating in cold weather are (1) indirect—steam heaters, and (2) direct—stoves, electric radiators.

The indirect method consists in by-passing the air from the supply fan through a chamber in which heating coils are placed. When it is desired to warm the air, steam is admitted to the coils and the by-pass is so altered that the air will circulate between the coils. In temperate climates it is rarely necessary to pass more than one-third of the air through the heater in order to obtain the desired temperature. Care must be exercised when such heaters are in use to prevent the overheating of the room air. In the British Navy a ventilation committee is in charge of such matters and this committee should take the necessary steps to secure adequate control of the heaters.

Captain Shaw is of the opinion that the combined system of heating and ventilation such as described is the most suitable for use on H. M. ships. He feels that this is distinctly superior to the employment of so-called steam or hot-water radiators. The same heating apparatus should not be used for several compartments unless the conditions affecting the temperature in each are approximately the same. The quantity of wild heat certainly has an important bearing on the design of the heat-supply system for each compartment.

Prior to the introduction of electricity, stoves were largely used for heating purposes, and coal-burning stoves of the closed type are still used in officers' messes and admirals' and commanding officers' apartments. The necessary draft up the flue should be insured by trimming the funnel of all stoves on deck; and when the funnel must be unshipped and the openings in the deck closed by a deck plate, care must be exercised to see that the fire is completely extinguished beforehand.

The electric radiator is a most valuable heater for use in submarines as well as surface ships. It is simple and clean and produces no products which pollute the atmosphere. In many other ways, also, does electricity aid in the problem

of naval hygiene by making it possible to obtain adequate lighting and improved air conditions and by the elimination of the pollution which would result from the use of lamps and candles. Wild heat throughout the ship has been reduced by the use of electricity in place of steam in many ways.

School Ventilation. Its Effect on the Health of the Pupil. Thomas J. Duffield. *American Journal of Public Health,* vol. 17, No. 12, December, 1927, pp. 1226–1229. (Abstract by Leonard Greenburg.)

This is a progress report of the committee on heating and ventilating of the American Public Health Association and was presented to that body at its fifty-sixth annual meeting at Cincinnati, Ohio (1927). The chief activity of the committee during the past year was an attempt at collaboration with the fresh air indoors committee of Rochester, N. Y., in a study of school ventilation. The American Society of Heating and Ventilating Engineers was also asked to colaborate in this study. Because of the fact that agreement between the American Public Health Association committee and the American Society of Heating and Ventilating Engineers committee on criteria for evaluation of ventilation was not forthcoming, a central conference committee on school ventilation, composed of seven members, was organized—three members from the American Society of Heating and Ventilating Engineers, two from the New York Commission on Ventilation, and one member each from the American Public Health Association and the joint committee of the American Medical Association and National Education Association. This central conference committee attempted to agree on a rating schedule or some other means of evaluating the conditions as found in window and fan-ventilated schools. The American Society of Heating and Ventilating Engineers proposed the use of a complex schedule based on air conditions maintained, whereas the other representatives favored a criterion based solely on the health of the school children. In view of this deadlock, the Rochester studies were dropped by the board of education of that city.

The American Public Health Association committee has been interested also in studies of school ventilation which were conducted by the New York Commission on Ventilation in Syracuse, N. Y., and Cattaraugus County, N. Y., and those conducted by the United States Public Health Service in New Haven, Conn. These studies agree in confirming the earlier studies of the New York State Commission on Ventilation in showing that, as gaged by the incidence of respiratory disease of the pupils, natural ventilation is superior to that produced by mechanical means under average conditions of operation.

The Cattaraugus County studies showed enormous differences in temperature between the floor and ceiling levels. In one case a difference of 45° F. was noted. The New York Commission on Ventilation plans to conduct experiments in an effort to maintain better air conditions in rural school rooms of this type.

Smoke and Air Pollution in a Modern City. H. B. Meller. *Pennsylvania's Health,* Pennsylvania Department of Health, vol. 5, No. 5, September–October, 1927, pp. 9 12. (Abstract by Leonard Greenburg.)

Smoke is the product of combustion, both solid and gaseous, emitted from the stack, and may include unconsumed carbon, various hydrocarbons, ash, sulphurous acid, chlorine, and ammonia. Part of this is visible and part may be invisible. The portion of the smoke which is visible is graded according to the Ringlemann Chart of the United States Bureau of Mines. Light smoke may be considered any which, while visible, is less than 60 per cent black. The atmospheric pollution to which people are subjected need not be only smoke, but, in addition, dust and pollution from other sources.

According to Doctor Meller, smoke and other substances which pollute the atmosphere irritate the sensitive membranes of the nose, eyes, throat, lungs, and gastrointestinal tract and diminish the potential reserve of the body. In addition to this, smoke and other solids in the atmosphere lessen the duration and intensity of sunshine and reduce the daylight which may be present. The importance of sunshine as a bactericidal and tonic agent is emphasized.

The systematic study carried on at the Mellon Institute showed that the average solid deposit throughout the city of Pittsburgh was approximately 1,000 tons per square mile per year. This was disclosed in the study undertaken in 1912. A resurvey in 1923–24 indicated that remarkable results had been obtained by the smoke ordinance. Visible smoke had been reduced approximately 60 per cent and dense smoke approximately 80 per cent, but the total deposit of solid matter (ash, iron oxide, and fixed carbon) had been increased practically 40 per cent. Doctor Meller points out that although now the visible smoke has been reduced, yet the increase in the solid particles constitutes an additional source of irritation to the respiratory membranes.

The author feels that a campaign of education, acquainting the general public with the gravity of the air-pollution evil, the provision of facilities to permit the control of visible smoke to the limit physically possible, and research by the chemist, the physician, and the engineer to cover thoroughly the field of air pollution, are the three requisites of the problem at this time.

Effect of different kinds of pipe on quality of water supplies. H. W. Clark. *Journal New England Water Works Association*, vol. 41, No. 1, March, 1927, p. 31. (Abstract by H. D. Cashmore.)

Investigations have shown that no matter what kind of pipe is used the water will take into solution a part of the metal, the amount depending somewhat on the water and the quality of pipe.

Iron pipe is affected the most, except when galvanized. Tin-lined pipes are the least affected. Much zinc is taken into solution from galvanized-iron pipe and brass pipe, which also yields a small amount of copper. From copper pipes only a small amount of copper is taken, but any zinc present is readily dissolved. Lead pipes have long been known to yield lead, and for this reason are dangerous, as 0.04 parts per 100,000 in solution will cause lead poisoning of some people when habitually used. Some doubt exists in the minds of different authorities as to the effect of copper and zinc on the human system.

As a matter of precaution it is suggested that where such dangers as the above exist the pipes be flushed thoroughly each morning before using the water. A small amount of copper is always present in the human system, coming from water and certain foods.

Use of Lime in Water Softening and Water Purification. Charles P. Hoover. Ind. Eng. Chem., 19:567–70, May, 1927. Abstract by Edward S. Hopkins in the *Journal American Water Works Association*, vol. 18, No. 6, December, 1927, p. 763.

"In addition to its softening qualities, attention is called to the sterilizing action of excess lime in water treatment. A selective action for *B. coli* is suggested, tables being given to show that after five hours' contact using excess causticity this organism is killed. Elimination of color, iron, turbidity, and odor and increased sedimentation efficiency are claimed. Modern practice is to soften to point of precipitation of magnesium and then add excess of carbon dioxide gas to precipitate calcium hydroxide, followed by filtration. Gas is obtained by burning coke, oil, etc. It is possible also to use 'split' treatment, neutralizing excess lime with carefully controlled portions of raw water. Operating cost of such treatment is given."

Recarbonation of Softened Water. Charles P. Hoover. Ind. Eng. Chem., 19:784–6, July, 1927. Abstract by Edward S. Hopkins in the *Journal American Water Works Association*, vol. 18, No. 6, December, 1927, p. 764.

"Water softened with lime may deposit calcium carbonate in pipe lines with decrease of capacity, or choke filter beds by formation of 'balls' resulting in poor operating conditions. Such a condition is overcome by adding carbon dioxide to such a supply, thereby converting the slightly soluble calcium carbonate to the highly soluble calcium bicarbonate. Such practice is being conducted in numerous places in this country, operating conditions of certain plants being

quoted together with a description of the apparatus, as well as a comparison of cost of various fuels for the production of carbon dioxide upon a plant scale."

DEATHS DURING WEEK ENDED FEBRUARY 11, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended February 11, 1928, and corresponding week of 1927. (From the Weekly Health Index, February 16, 1928, issued by the Bureau of the Census, Department of Commerce)

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Data for 67 cities.
[4] Deaths for week ended Friday, Feb. 10, 1928.
[5] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Louisaille, 17; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; and Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

Indiana	66
Maine	74
North Dakota	18
Vermont	64

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 101 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 31,650,000. The estimated population of the 95 cities reporting deaths is more than 30,960,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended February 4, 1928, and February 5, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
43 States	2,282	2,155	
101 cities	1,152	1,156	1,082
Measles:			
42 States	14,034	12,413	
101 cities	4,384	3,397	
Poliomyelitis:			
43 States	59	13	
Scarlet fever:			
43 States	5,166	6,469	
101 cities	1,635	2,397	1,504
Smallpox:			
43 States	1,338	1,374	
101 cities	127	118	103
Typhoid fever:			
43 States	226	208	
101 cities	42	43	39
Deaths reported			
Influenza and pneumonia:			
95 cities	1,0[illegible]	1,088	
Smallpox:			
95 cities	1	0	
Terre Haute	1	0	

City reports for week ended February 4, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics, or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during non-epidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population, July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

[1] Typhus fever: 1 case at Baltimore, Md., and 2 cases at Savannah, Ga.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended February 4, 1928, compared with those for a like period ended February 5, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927

and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, January 1 to February 4, 1928—Annual rates per 100,000 population, compared with rates for the corresponding period of 1927 [1]

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended January 21, 1928.—The following report for the week ended January 21, 1928, was transmitted by the Eastern Bureau of the Health Section of the Secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt.—Suez.
Madagascar.—Tamatave.
Aden Protectorate.—Aden.
India.—Bassein, Bombay, Rangoon.
Ceylon.—Colombo.
Dutch East Indies.—Makassar.

India.—Calcutta, Rangoon.
Straits Settlements.—Singapore.
Siam.—Bangkok.
French Indo-China.—Saigon-Cholon.

Ceylon.—Colombo.
China.—Shanghai.
French India.—Pondicherry.
India.—Bombay, Madras, Calcutta, Cochin, Rangoon, Moulmein, Vizagapatam.
French Indo-China,—Saigon-Cholon.
Dutch East Indies.—Belawan-Deli, Banjermassin, Pontianak.
Iraq.—Basrah.
Sarawak.—Kuching.
China.—Hong Kong.

Returns for the week ended January 21 were not received from Canton, China, or Vladivostok, Union of Socialist Soviet Republics.

ARABIA

Aden—Plague—January 9–17, 1928.—Plague was reported present at Aden, Arabia, January 9, 1928. The outbreak was stated to have occurred in a section of the town inhabited by coal coolies. All of the residents of this section were removed to Flint Island and isolated. On January 17 a small increase was reported in the number of cases first reported, occurring in the original infected area.

Quarantine and restrictive measures taken.—The section in which the outbreak occurred was stated to be under police guard. Quarantine measures applied to vessels in port were stated to be:

1. Medical inspection prior to embarkation of all passengers and members of crew joining the ship at Aden;
2. Disinfection prior to loading of merchandise considered liable to convey infection;
3. No visiting passengers allowed on shore and no persons allowed on ship other than those required for work on the vessel except under special permission of the port health officer.

ARGENTINA

Plague—Rosario—February 20, 1928.—A report of a case of bubonic plague at Rosario, Argentina, was received on February 20, 1928.

BRAZIL

Plague—Rio de Janeiro—February 16, 1928.—Under date of February 16, 1928, three cases of plague were reported at Rio de Janeiro, Brazil.

CANADA

Communicable diseases—Week ended February 4, 1928.—The Canadian Department of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended February 4, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever			1	1				2
Influenza	14			6				20
Lethargic encephalitis				2				2
Poliomyelitis							3	3
Smallpox				63		9	1	73
Typhoid fever	1	1	21	19				42

Quebec—Communicable diseases—Week ended February 4, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended February 4, 1928, as follows:

Disease	Cases	Disease	
Cerebrospinal meningitis	1	Scarlet fever	112
Chicken pox	21	Smallpox	11
Diphtheria	45	Tuberculosis	26
German measles	6	Typhoid fever	21
Influenza	1	Whooping cough	11
Measles	208		

CUBA

Habana—Communicable diseases—January, 1928.—During the month of January, 1928, communicable diseases were reported in Habana, Cuba, as follows:

Disease	New cases	Deaths	Remaining under treatment Jan. 31, 1928	Disease	New cases	Deaths	Remaining under treatment Jan. 31, 1928
Cerebrospinal meningitis			1	Measles	8		7
Chicken pox	7		6	Paratyphoid fever	2	1	1
Diphtheria	8	1	4	Scarlet fever	1		1
Leprosy			18	Typhoid fever [1]	33	2	45
Malaria [1]	43	2	7				

[1] Many of these cases from the interior.

DUTCH EAST INDIES

Plague—Island of Java—November 19–December 10, 1927.—During the period November 19 to December 10, 1927, plague was reported present in the Island of Java, Dutch East Indies, as follows: *Pasoeroean Residency*—November 28 and December 10, 1927, in two native villages in the Tengger District. *Surakarta Residency*—November 19, 1927, in 13 subdivisions and Klaten District. *Surabaya Residency*—at Grissae, a seaport town, December 1, 1927.

ECUADOR

Guayaquil—Plague—Examination of rats—Smallpox—December 16–31, 1927.—During the 16 days ended December 31, 1927, five cases of plague with two deaths were reported at Guayaquil, Ecuador. During the same period, of 11,634 rats taken, 11 rats were found plague infected.

During the same period, four cases of smallpox were reported at Guayaquil.

EGYPT

Suez—Plague—January 18, 1928.—A fatal case of plague occurring in a native who was found dead in his own house was reported at Suez, Egypt, January 18, 1928. The locality is 4 kilometers from the port.

JAMAICA

Smallpox (Alastrim)—January 1–28, 1928.—During the four weeks ended January 28, 1928, eight cases of smallpox (alastrim) were reported in the island of Jamaica, exclusive of Kingston.

Other communicable diseases.—During the same period other communicable diseases were reported in the island as follows:

Disease	Kingston	Other localities	Disease	Kingston	Other localities
Chicken pox	3	23	Puerperal fever		1
Diphtheria		1	Tuberculosis	19	39
Dysentery	3	11	Typhoid fever	22	72
Leprosy		1			

Population, island, estimated 926,000 Kingston, census, 62,707

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

INFANT AND MATERNAL MORTALITY IN THE UNITED STATES

By E. BLANCHE STERLING, *Acting Assistant Surgeon, United States Public Health Service*

INFANT MORTALITY

The accompanying graphs show the downward trend in infant mortality during the 10 years from 1915 to 1924. The provisional figures for 1925 and 1926 show a slight rise; but in view of the fluctuations shown in the curves this is probably not significant. In the period for 1915 to 1924, for which we have complete data for the white and colored races in both rural and urban areas, it will be seen from the table and graphs that there was a decrease of 29 per cent in the total infant mortality rate in the registration area. The decreases in the rates for the urban and rural areas were very similar—30 per cent for the urban and 27 per cent for the rural. The improvements in the rate for white infants in the total registration area, in the urban area, and in the rural area are strikingly similar—32 per cent, 32 per cent, and 31 per cent, respectively.

With the exception of urban areas, the rate for colored infants has decreased to a greater extent than has that for white infants. The improvement in rural areas is striking. The mortality rate among colored babies in the country has decreased 42 per cent in the decade under consideration. This is interesting in view of the fact that undoubtedly no class of the infant population has been less affected by so-called infant welfare work. It apparently behooves us to learn what is lacking in our present methods, or, to be more fundamental, what are the most important causes of infant mortality. It may be that we are spending our ammunition on snipers while the heavy battalions of the enemy are mowing down our lines.

It is doubtless true that improper feeding is responsible for a part of the infant mortality. The studies of the United States Public Health Service in the use of dried-milk powder in infant feeding pointed the way to a possible lowering of infant mortality from intestinal causes by a wider use of this product in localities where pure fresh milk is not available.

A very large proportion of the total infant mortality takes place within the first month of life. The Public Health Service has recently

issued a statistical study of the problem of fetal and neonatal death which sums up our present knowledge of the subject.[1] This study emphasizes the need of further research.

MATERNAL MORTALITY

Unfortunately the United States can not show a downward trend in maternal mortality. In fact, the accompanying tables and graphs show a rise of 8 per cent in maternal mortality from all puerperal causes in the total registration area from 1915 to 1924. In urban areas there has been a rise of 14 per cent—from 6.4 to 7.3 per 1,000 live births. The rural areas show an increase of 5 per cent. The only decrease shown in the maternal mortality from all puerperal causes is in the rate for white mothers in rural sections, which has fallen from 5.5 to 5.1—a decrease of 7 per cent. In the total registration area the rise in the rate for whites is very slight—less than 2 per cent—but in urban areas alone the rise has been 11 per cent.

Puerperal septicemia	6.3	6.7	7.0	6.5	5.8	6.6	6.8	5.7	5.8	5.8

A study of the rates for colored mothers shows increases in the total registration area, in the urban, and in the rural area, of 11 per cent, 17 per cent, and 34 per cent, respectively.

A study of Tables 2, 3, and 4 shows that of the maternal mortality due to all puerperal causes in 1924 in the total registration area, that due to puerperal septicemia comprised over 36 per cent of the total, and more than 58 per cent of that due to all other puerperal causes. This appears to be the greatest single cause of puerperal mortality, but Table 3 does not indicate that this cause accounts for the slight rising trend of maternal mortality. Though there is a slight increase from this cause in the total urban rate and in the rates of white city women and colored country women, in every other instance the rates show a tendency either to fall or to remain more or less stationary.

It is possible that an examination of other causes of puerperal mortality may shed some light on the question. Data for the rates per 1,000 live births for the specific causes of puerperal mortality are not available, but the death rates per 100,000 estimated population from these specific causes are shown in Table 5. These include the more important causes of puerperal mortality and cover the same period under consideration, 1915–1924.

In two of these causes—other accidents of labor (puerperal hemorrhage having been eliminated) and albuminuria and convulsions—

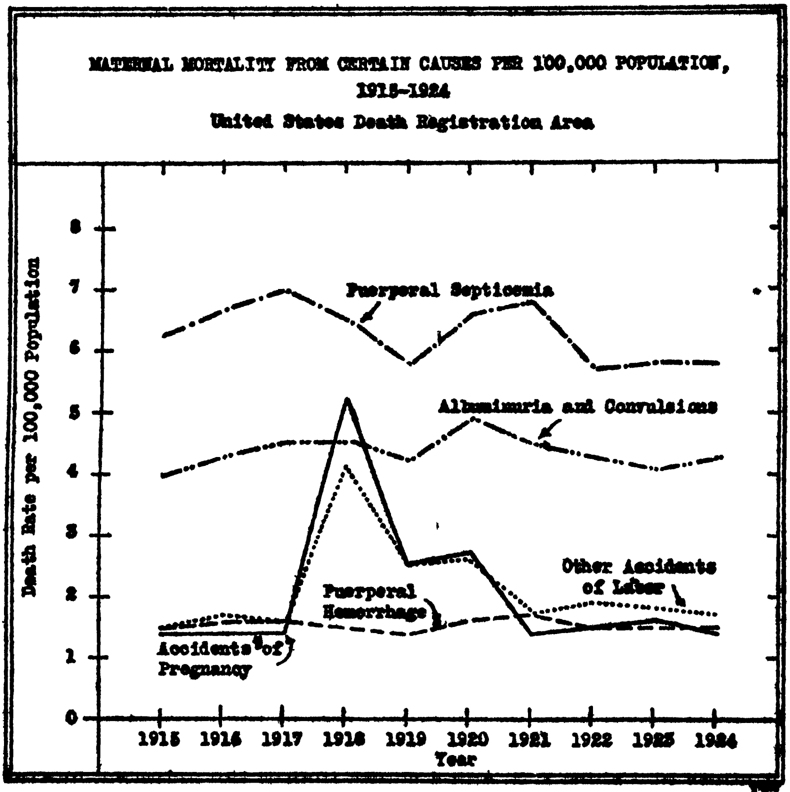

FIG. 3

there seems to be a slight rising tendency. The rate for the former has risen 13.3 per cent and for the latter more than 7.5 per cent. The indications are that the more careful management of normal labor and its complications should be emphasized in any endeavor to reduce the death rate from puerperal causes.

BIRTH AND DEATH REGISTRATION

There continues to be a gradual expansion of the birth and death registration areas, and the birth registration area has almost caught up with the death registration area. There are now 42 States, the

District of Columbia, and 21 registration cities in nonregistration States in the death registration area. This includes 91.3 per cent of the total population of the United States. Of the remaining 6 States, 4 have good registration laws which have not been in force long enough to bring registration up to 90 per cent, as required for acceptance into the registration area, and 2 have unsatisfactory laws which can not secure good registration.

In the birth registration area there are 40 States and the District of Columbia, which, together, include 87.3 per cent of the total population of the country. Six other States have good laws which are yet too new to have brought the registration of births up to the required 90 per cent. Two States have unsatisfactory laws. Considerable progress was made in stimulating both death and birth registration during 1927, one State having been added to the death registration area and five States to the birth registration area. The Bureau of the Census is carrying on a special campaign looking toward the inclusion of every State in the registration area before 1930.

MALTA FEVER: A PROBLEM FOR STATE AND MUNICIPAL LABORATORIES

By A. V. Hardy, M. B. (Tor.), *Acting Assistant Surgeon, United States Public Health Service, Iowa State Epidemiologist, Acting Director Iowa State Laboratories*

There is, at present, a growing interest in Malta fever. This began in 1924, when Keefer (1) published the report of a case due to *Br. melitensis* var. *abortus*. The previous work of Evans (2), who established the close relationship between the *Br. melitensis* of Malta fever and the organism of contagious abortion of cattle, suggested this possibility. Much work has since been done in the attempt to prove the source of the few scattered human cases which have been diagnosed in this country, and different conclusions have been reached. The prevalence of contagious abortion in cattle and the apparent infrequence of Malta fever has caused some investigators to question the etiological relation of the former to the latter. Others, however, agree with Huddleson (3) who suggested that there have been, and now may be, many cases of this disease which are not diagnosed. The lack of pathognomonic symptoms or signs makes this probable. The findings of Hull and Black (4), Orr and Huddleson (5), and our own, support this opinion. It is urged by See (6) that the disease simulates typhoid, paratyphoid, influenza, acute articular rheumatism, tuberculosis and certain forms of malaria. Because this is true, Evans (7) has pointed out that "there is no disease in which the physician is more dependent upon laboratory findings for a correct

diagnosis," and has also advised that more examinations for Malta fever be done.

The State and municipal laboratories have an unusual opportunity to contribute to the study of Malta fever. Blood will be received from a large proportion of patients with a prolonged undiagnosed fever. At the present time, few general practitioners think of the possibility of meeting Malta fever, but typhoid or paratyphoid will be considered. Having these in mind, blood will be sent for a Widal test. Our findings indicate that in all such cases an examination for Malta fever should be done. The laboratory should take the lead here and investigate in a direction not requested by the physician. Only when the disease becomes generally known and clinically suspected should the laboratory worker wait for the physicians to request the examination.

In tabular form the findings for six months at the Iowa State Laboratory are summarized. During this period, blood specimens sent for Widal tests were examined for Malta fever. The difference in the number of tests which were made during the first three months and the last three months demands explanation. Eighty per cent of the specimens received are dried blood. During the first three months only wet blood specimens were tested for Malta fever. The probability of detecting additional cases through the examination of dried blood suggested itself, and this was started early in September. On the first day that this was done, one specimen gave a marked agglutination of the organisms, so the procedure has since been adopted as a routine. The technique and the interpretation of the tests will be discussed in a later part of the paper.

Results of blood examinations for Malta fever at the Iowa State Laboratory during a six-month period

Month	Agglutination tests for Malta fever	Positive agglutination tests	Positive cases	Confirmed positive cases	Unconfirmed positive cases
June	32	4	3	2	1
July	27	5	2	2	0
August	37	3	2	2	0
September	211	22	8	6	2
October	256	15	12	10	2
November	220	19	11	9	2
Total	783	68	38	31	7

In the second column of the table the total number of positive agglutinations reported is indicated. The difference between these numbers and the total number of positive cases is explained largely by the repetition of examinations on the various cases. In September, however, five dry blood specimens were recorded as weakly positive, but the wet blood specimens from these patients proved to be nega-

tive. These had been reported without titration by the method which will be described. The specimens were kept, however, and later, in October, the titer was determined and they were found to fall into the class now reported as negative.

The positive cases are divided into two groups—confirmed positives and unconfirmed positives. In many of the cases, the agglutination of *Br. melitensis* has suggested the diagnosis of Malta fever. On this basis alone, however, the diagnosis is not established. Clinical evidence pointing to Malta fever and laboratory and clinical evidence ruling out the diseases with which it may be confused, combined with the laboratory evidence of the infection, are considered as sufficient to confirm the diagnosis. The clinical findings were personally determined in 21 cases. This was done during an epidemiological investigation. In 20 of these, the clinical findings justified the classification of the case as a confirmed positive. The one regarded as an unconfirmed positive had an advanced carcinoma, but with a persistent low-grade fever. The latter may have been due to *Br. melitensis*, but the agglutination titer was never higher than 1:160, and two cultures proved to be negative. Of the remaining 11 confirmed positive cases, 2 were studied in the University of Iowa Hospital and the organisms were repeatedly isolated. On seven, two or more agglutination tests were done and in addition a clinical report has been sent by the physician. A recent case with a high titer is included on the basis of laboratory evidence alone. One case, on which the agglutination test on the dried blood only was done, is considered as confirmed, since the clinical signs, symptoms, and course all indicated Malta fever. A wet blood specimen could not be obtained from the patient

All positive serums have been tested with five organisms: *Br. melitensis*, var. *melitensis; Br. melitensis* var. *abortus; B. typhosus; B. paratyphosus* A; and *B. paratyphosus* B. Serums from 21 of the confirmed positive cases were tested with *B. tularense*. In all cases there was no agglutination of typhoid or paratyphoid organisms. In one case, *B. tularense* agglutinated in the 1:20 dilution and slightly in 1:40, but not higher. With *Br. melitensis* var. *melitensis* and var. *abortus*, there have been almost corresponding results in the titer obtained. With these organisms in 11 of the confirmed cases a titer of 1:1,280 was obtained; in four 1:640; in ten 1:320; in three 1:160, and in two 1:80. The reaction is called positive if there is a precipitation of 75 per cent or more of the antigen.

The unconfirmed positive cases are largely so classed because they have not been sufficiently studied. Serums from the one case in June and the two cases in September were examined both by us and at the Hygienic Laboratory, in Washington, D. C. Two gave a titer of 1:640 and one 1:80. No clinical history is known, however, but

these are probably Malta fever. The remaining four cases include two on which only positive dry blood specimens have been received, one on which the serum titer was 1:80, and the carcinoma case, previously mentioned.

ROUTINE MACROSCOPIC TEST

Many, if not most, of the public health laboratories are understaffed. Already there is a burden of work for each person. To be applicable, therefore, any additional routine tests must be simplified as far as is compatible with the obtaining of accurate results. It should be remembered, however, that very valuable contributions to our present knowledge of Malta fever may be made by standardized routine work. It is evident that to examine all specimens, a rapid method must be used; but a careful study should be made of all suspicious or positive specimens. To meet these requirements, the procedure described below has been found satisfactory.

In the preparation of antigen for routine work we have used an *abortus* strain supplied by the Hygienic Laboratory at Washington, and known as No. 456. We follow essentially the procedure described by Evans (7). From the stored supply a dilution is made to compare with the opacity standard of 1,000 p. p. m. For the preliminary examination of all specimens this antigen is diluted with equal parts of saline. This gives a suspension of 500 p. p. m. The serum is then diluted directly in the antigen. For each test, 5 tubes, 11 by 90 millimeters, are used. The serum dilutions are 1:5, 1:10, 1:20, 1:40, and 1:80. Three tubes only would be satisfactory, using the 1:20, 1:40, and 1:80 dilutions, but the five are used in order to collect data on the agglutination in low titers. A final volume of 0.4 c.c. is satisfactory and has the advantage of using less antigen. The dilutions are made as would ordinarily be done in saline. The method followed in this laboratory is to pipette the diluted antigen, using a 5 c. c. pipette graduated in 0.1 c. c. To the tubes in order 0.8, 0.4, 0.4, 0.4, and 0.2 c. c. are added. Using these amounts there is sufficient antigen in the 5 c. c. for two tests. Using a 1 c. c. pipette graduated in 0.01 c. c. to the first tube 0.2 c. c. of serum is added, giving the 1:5 dilution. From this tube 0.4 c. c. will be transferred to the second tube, giving the 1:10, and in a similar manner the 1:20 and the 1:40 dilutions are obtained. Of the 0.4 c. c. withdrawn from tube four, only 0.2 c. c. is added to tube five, giving the 1:80 dilution. The remaining 0.2 c. c. withdrawn is discarded. After the dilutions are thus set up, the racks are mechanically shaken for five minutes. They are then transferred to the 37° water bath and left for four hours. After this they are removed to the cold room and readings are made the following morning. In this preliminary test,

if there is agglutination in a titer of less than 1:40, a negative report is usually made, but with the suggestion that the examination be repeated if the fever continues. Only to hospitals or clinics in which a bacteriological study would be possible are agglutinations of 1:10 and 1:20 reported. It is indicated in the report that this titer has probably no diagnostic significance; but since positive cultures have been reported from such cases, it is suggested that cultures be taken. All serums which show complete agglutination in 1:40 and complete or partial in 1:80 are retitered before the report is made.

Before the final titration, serums are inactivated at 56° for 30 minutes. This should always be done if the 37° bath is used in the test. Three serums have been found by us which gave agglutinations up to 1:80 in the preliminary test, but which reduced to a titer so low as to be of no diagnostic importance after inactivation. Occasionally, therefore, misleading reports would be made if this step were omitted. In this titration, serums are first diluted in saline and the 1,000 p. p. m. antigen is added. As a matter of study, testing with both *abortus* and *melitensis* antigens is here recommended, though for diagnostic purposes only, either would be satisfactory. The shaking, incubation, and reading are done as described for the routine tests.

Of first importance in the interpretation of the macroscopic test is a knowledge of the lowest diagnostic titer. In order to determine this, a study of serums sent for Wassermanns has been started. At present, 287 tests have been done; but of all, 49 per cent gave complete agglutination in 1:5, 30 per cent in 1:10, 9.8 per cent in 1:20, 1.4 per cent as high as 1:40, and one specimen, or 0.3 per cent, had complete agglutination in 1:80 and partial in 1:160. Further work is being done to verify these results and to explain the phenomenon. The results suggest, however, that agglutination in a titer of less than 1:80 has little diagnostic value, and both the laboratory worker and the physician would be well advised to be slow in making a diagnosis of the infection because of agglutination in a low titer.

In the reporting of laboratory findings it must be borne in mind that some practitioners will accept any unqualified positive report as conclusive evidence of the presence of a disease. Until, therefore, more is known of the significance of agglutination in different titers, a letter should be sent with a positive report. This should urge that a diagnosis of Malta fever be made only if clinical and laboratory findings agree. The laboratory may assist in the differential diagnosis by reporting on typhoid, paratyphoid, and tularaemia; but the clinician must rule out an incipient tuberculosis, influenza, and, in some districts, malaria. If a titer of 1 : 80 only has been obtained, additional caution should be urged, though it may be pointed out that a diagnosis of the infection may safely be made if the clinical findings strongly support the laboratory suspicion. In the letter

giving a positive report, it is well to suggest that blood counts and cultures would be helpful, and in most instances it is appropriate to request that full clinical notes be kept. At this time also the epidemiological investigation may be mentioned; and for its success, the physician's interest and cooperation should be invited. Through such a personal letter with the report, a real cooperation may be enlisted.

MICROSCOPIC AGGLUTINATION TESTS

In the microscopic, as in the macroscopic test, two methods are employed. The first is simple and rapid and made on all dry specimens to separate the negative from the suspicious specimens. A titration on the latter is done before the final report is made. For all microscopic tests an antigen of 1,000 p. p. m. is used. In the first test a part of the dried blood is dissolved in a small drop of saline. Using a loop, the blood is mixed with the saline until the color of a drop in the loop compares with that of pale vaseline. This will give a final dilution of approximately 1 : 40. Care is necessary if errors are to be avoided, but an experienced worker can do this test with sufficient accuracy to separate negatives from the suspicious or positive specimens. The hanging drop is prepared in the usual manner and incubated for one hour. In this time there seems to be as much clumping as takes place in four hours, and tests are much easier to read after one hour than after four hours. Following a long incubation there is usually a precipitation of moisture around the hanging drop and this makes the reading difficult. In this preliminary examination any clumping is considered as suspicious, and on all of these a titration is done. The remainder are reported as showing no agglutination.

In the titration of dry bloods the dilution must be made on the basis of a color comparison. The method used is a modification of that described by Wadsworth (8). In this laboratory 0.02 c. c. of the defibrinated sheep blood is used, and, after drying, is diluted with 0.18 c. c. of saline. This gives the 1:10 color standard. This standard is then diluted to give the 1:20, 1:40, and 1:80 colors. In making this dilution, a Pasteur pipette is used. With this pipette held at a constant angle, two drops of saline are delivered into each of three depressions in the porcelain plate. The pipette is then blown dry. Two drops of the 1:10 standard are transferred to the second depression, giving the 1:20 dilution. In a similar way the 1:40 and 1:80 standards are obtained. A fresh specimen is also diluted, using the same procedure. This is necessary, since the old dry blood presents a much darker and browner appearance. With the two standards, however, a fairly accurate comparison of colors may be made. Following this procedure there will be equal volumes

in the 1:20, 1:40, and 1:80 dilutions, and a color comparison is, for this reason, easily made.

The dry blood to be titered is dissolved with saline. This should be added ten minutes or more before the titration is to be made. A volume estimated as sufficient to give a dilution of approximately 1:10 is used. Care should be taken not to add enough to give a dilution higher than this. Additional saline may be added in the porcelain diluting plate until the color compares with the standard. Dilutions are made in the same manner as that described for the standard. Dilutions up to 1:160 should always be made, but we have found it interesting to titer up to 1:1280. The result of the titration of positive serums and the positive dry bloods which have been obtained from the same patient may then be compared. This knowledge will be of value in interpreting the results of the dry blood examinations. In making the test, the hanging drops are prepared in the usual way. A loopful of the dissolved blood is mixed with a loopful of antigen. The lowest dilution set up will therefore be 1:20.

In reading, after the controls have been observed, the presence or absence of clumping in the test drops is noted. If this is present, the size of the clump is observed and recorded as small, medium, or large. The presence or absence of free organisms should also be noted. If there is any uncertainty, high power observations should be made. There are many possible errors in the interpretation of a microscopic agglutination test done on a small nonmotile organism. Great caution should therefore be used. At the present time we consider it unwise to make an unqualified positive report. The physicians are informed, by letter, of the significant findings, but we indicate that there has not been sufficient experience with the test to learn its reliability. We request that, in order to confirm the report, wet blood be sent for the macroscopic test. This is almost invariably done. If the agglutination tests on the dried blood are made, it is important that the laboratory have a standard which will allow a classification of the tests as negative, doubtful, or positive. This standard adopted at present may be changed after more experience. Through an examination of the dried smears made from the whole wet bloods received, the serum titers of which have been determined, we have fixed a standard satisfactory as a working basis. Tests which show small clumps in the lowest dilution with no agglutination in the higher are regarded as negative. This will be obtained when the serum gives complete or partial agglutination in a 1:20 dilution. Those showing medium or large clumps in the 1:20 and 1:40 dilutions, with small clumps and some free organisms in 1:80 or up to 1:160, are regarded as suspicious and should be reported; but if there are medium and large clumps in 1:40 and 1:80, with large, medium, or small clumps, but complete agglutination in 1:160, it may be expected that the case will prove to be Malta fever. At the

present time, however, as has been indicated, a final opinion should not be based on an examination of the dried blood only, but this standard may be used as a basis for further study and will prevent the giving of misleading information to the physicians.

DISCUSSION

The findings made at the Iowa State Hygienic Laboratories as a result of the routine examination for Malta fever of blood specimens sent for Widal tests have been reported. The significance of these examinations is better realized when compared with the results of typhoid examinations. During the three months, 46 positive Widals were reported from 41 cases, while the number of agglutinations for Malta fever was 56 from 31 cases. The figures indicate that, in Iowa at least, Malta fever presents a health problem comparable to that of typhoid.

The advisability of adopting the routine described in all State and municipal laboratories is emphasized by this report. Of the 38 positive cases, in only 10 did the physician consider Malta fever as a possibility and request the agglutination test. This condition continued even though a case was reported and discussed at the meeting of the State medical society in June, 1927, and the report later appeared in the Journal of the Iowa State Medical Society. The laboratory has also at different times, through brief laboratory notes which are inclosed with reports, called the attention of the physicians to the possibility of encountering Malta fever. Many physicians, therefore, have been looking for the disease. Even after this, in not one-fourth of detected cases had any examination for Malta fever been requested by the physician. The State and municipal laboratories should, therefore, make this examination as a routine. The advisability of testing the dried bloods may also be urged. In the three months in which this has been done, 30 positive cases have been found. Of these, 19 were first detected through the examination of the dried blood sent for a Widal test.

In Iowa, and the same is probably true of most States, many bloods are examined at hospital and private laboratories. For study we have requested that these be sent to the State Laboratory for Malta fever examination only. This has resulted up to the present in the finding of four cases. It seems advisable at the present time to have all examinations for this infection done at central laboratories. Cases may then be studied more fully and accurately.

The diagnosing of a greater proportion of the cases of Malta fever which actually occur may modify the present conception of its clinical course. In the past, only the unusually severe and prolonged cases have been studied. Those which were milder and shorter did not call forth the additional thought and action which might have led to the correct diagnosis. It may become clear,

therefore, that many mild and comparatively short illnesses are due to *Br. melitensis.*

Malta fever is probably a disease of the country, villages, and small towns. Most cases will, therefore, be seen by the general practitioners. Their laboratory in Iowa is the State laboratory, and a similar situation probably exists in most States. To obtain their interest in the infection, the most effective means will be to suggest and confirm the diagnosis of Malta fever on cases in which this disease was not clinically considered. This will be done only when bloods sent for Widal tests are routinely tested with *Br. melitensis.*

The distribution of the infection is as yet unknown. This information might soon be gathered by a united interest and effort taken by State and municipal laboratories. Negative findings will be as valuable as positive. A correlation of the distribution of Malta fever with that of contagious abortion will provide important information in the epidemiology of the disease. In addition, preventive measures will be taken only when its prevalence is known. This situation demands the diagnosis of the cases, and unless the laboratory takes the lead, this will rarely be made. The opportunity of contributing to the present knowledge of Malta fever, and of aiding in its control, is therefore apparent.

CONCLUSIONS

1. An examination for Malta fever should be done routinely on all blood specimens sent to State or municipal laboratories for Widal tests.
2. A rapid and preliminary test may be made to eliminate the negatives, but a careful study should be made on all doubtful and positive specimens.
3. Dried blood specimens as well as serums should be examined. The procedure for this test is described.
4. A diagnosis should be established only if clinical and laboratory findings agree.
5. Malta fever in Iowa presents a health hazard comparable to that of typhoid.
6. State and municipal laboratories have an unusual opportunity in contributing to the study of Malta fever.

SECOND INTERNATIONAL CONGRESS OF RADIOLOGY

To Be Held in Stockholm, Sweden, July 23–27, 1928

The attention of persons and institutions interested is invited to the Second International Congress of Radiology which will be held in Stockholm, Sweden, from July 23 to 27, 1928.

According to a memorandum furnished by the Minister of Sweden, through the Department of State, the proceedings will comprise Röntgen diagnosis, radiotherapy (including Röntgen, radium, and helio therapy), medical electrology, radio physics, and instruction in medical radiology. Summary addresses will be given on different branches of radiology and a series of papers will be presented on instruction and training in medical radiology, with particular reference to experiences gained in the different countries.

The question of establishing an international unit dosage for Röntgen rays, as well as the question of general principles for protective measures, will also be a subject of discussion during the proceedings.

The congress will be held in the House of Parliament.

Persons intending to participate in the congress may secure additional information and a membership card, for which a small charge is made, by addressing the Secretary General, Second International Congress of Radiology, Sophiahemmet, Stockholm, Sweden.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Recent Trend in Sewage Disposal Developed in Design for Fostoria, Ohio. J. F. Laboon. Proceedings of the Engineers Society of Western Pennsylvania, vol. 43, No. 3, April, 1927, pp. 149–178. (Abstract by Fred Almquist.)

Of the more important developments in the art of sewage disposal the following are mentioned: The detritus tank for the interception of grease and grit; the separate digestion of sludge; and the means for digestion of large quantities of sludge as in the activated sludge type of disposal. The second will be adopted for the proposed plant of Fostoria, Ohio.

After reviewing the various stages in the construction of sewage disposal facilities at Fostoria, the author comments on an acid sewage which occurred from time to time and which deleteriously affected all physical fixtures below the flow line. The acid sewage was caused by a particular industry, which later installed a lime neutralization plant. In 1926 the city was restrained from using Portage River as a receiving basin for the effluent from their disposal plant Consequently, additional disposal facilities had to be sought.

The new improvements consist of grit-handling apparatus, transformation of an Imhoff tank into a separate sludge digestion tank, thickeners, dosing tanks, trickling filters, humus tank, and some others less important. Digestion in the separate sludge tank will be hastened by heating in the winter. The heater will be arranged to use gas collected from the digestion tank. Lime will be added to obtain optimum hydrogen ion concentration of the sludge for the elimination of acid digestion. Trickling filter rate is 2,500 people per acre per foot of depth on a basis of an average depth of 7 feet.

Wet Sludge as Fertilizer. S. Duxbury. *Public Works*, vol. 58, No. 10, October, 1927, pp. 374-375. (Abstract by R. J. Faust.)

The fertilizer value of wet sludge, 95 per cent moisture, from the Bedford, England, sewage treatment plant is 87 per cent greater than similar sludge air dried, 28 per cent moisture, as determined by actual experiments. The elevation of the sludge outlet valves at the plant are above the surrounding land so that it is possible to discharge the wet sludge on the land by gravity. The advantages claimed by this method of sludge disposal are— (1) Sludge is never so valuable for fertilization as when fresh; (2) it can be more evenly distributed; (3) fresh sludge warms cold soils, makes them more porous, and the fermentations that take place during decay tend to make the soil more mellow; (4) the plant food is more available; (5) when spread evenly and thinly, there is no loss of its valuable constituents through early fermentation; (6) the crop is more even; (7) it improves the mechanical condition and drainage of the soil; (8) it is disposed of with advantage at a low cost.

Operating Results of the Essen Activated Sludge Plant. Karl Imhoff. (Translated from the German by Gordon M. Fair). *Engineering News-Record*, vol. 99, No. 20, November 17, 1927, pp. 790-791. (Abstract by C. H. Kibbey.)

The activated sludge plant at Essen-Rellinghausen has been in operation since December, 1925, serves 45,000 people, and receives a dry-weather flow approximating 130 gallons per capita per day. The wooden paddles (mechanical agitation device) used in conjunction with compressed air have continued to show their usefulness. With a three and one-half hour aeration period the air consumption is only 0.08 cu. ft. per gallon, and the entire power consumption is 7 h. p. per m. g.

The analytical results, which are comprehensively stated in a table, show a reduction in suspended solids of from 180 p. p. m. in raw sewage, and 120 p. p. m. in Imhoff tank effluent, to 6 p. p. m. in effluent from the activated sludge plant. Consumed oxygen is shown as 532 p. p. m. in raw sewage, 350 p. p. m. in Imhoff tank effluent and 30 p. p. m in effluent from the activated sludge plant. The hydrogen ion concentration remains relatively the same for raw sewage, Imhoff tank effluent and effluent from the activated sludge plant being expressed as pH 7.5 for both raw sewage and tank effluent and 7.2 for activated sludge plant.

Heating is accomplished by raising the temperature of water from the pressure supply mains, in a boiler heated by sludge gas, to 70° or 80° C., and then introducing it into the bottom of the digestion tank. This obviates the difficulties experienced where heating coils are passed through the sludge. The temperature in the sludge tank, which was 8° to 9° C. prior to heating, has since been maintained at 21° C., with a tenfold increase in gas production and consequent increased digestion tank efficiency. Only that gas generated in the digestion tank is used in this way. Gas from the Imhoff tanks is sold to the municipal gas works. Since heating has been introduced, the total gas production has been increased, the CO_2 content of the gas has increased somewhat, and the methane content remains over 73 per cent.

The construction cost, exlusive of preliminary clarification units, is now $90,000, with an operating cost of $12,500 per annum.

Sewage Disposal in the Lower Lea Valley, Essex. Anon. *Surveyor*, vol. 72, No. 1866, October 28, 1927, pp. 391-392. (Abstract by R. E. Thompson.)

A new outfall sewer was recently put into commission in Leyton for delivering the sewage of the district into the London County Council system. The work is the culmination of negotiations which have been proceeding since 1906. The arrangements were completed in conjunction with the Walthamstow Council. Venturi recording apparatus and electrically-controlled cutting-off gear have been provided, the latter diverting sewage into stand-by storage tanks when the

sewage in the London County Council sewer reaches a predetermined level and when rate of flow from Leyton exceeds a specified amount (50 gallons per day per head of population upon an agreed figure). The average length of time during which the sewage has been at the specified level for several years is about 14 hours per annum. When the level recedes, the sewage from the tanks, which have total capacity of over 2¼ million gallons, flows back into the county council sewer.

Conditions at Sewage Works of Milwaukee, Wisconsin. Robert Cramer. *Engineering News-Record*, vol. 99, No. 19, November 10, 1927, p. 751. (Abstract by D. E. Kepner.)

In a paper read before the Lake Michigan Sanitation Congress, abstracted in this article, the author states that the purification possibilities of the activated sludge process are being demonstrated on a large scale at the Milwaukee plant. An average of 70 m. g. d. was being treated at the time the paper was prepared, or about 75 per cent of the then dry-weather flow. By increasing the capacity of some of the sludge dewatering apparatus and correcting certain faulty designing, the capacity of this part of the process will be increased to permit operation of the entire plant at full dry-weather-flow rate.

Changes and additions being made to permit more efficient operation include the rebuilding of the drier settings so that the excess air necessary for drying is mixed with gases of combustion in the furnace, resulting in lower furnace temperatures and increasing the life of the fire brick. Troublesome odors from the drier discharges were being treated with chlorine gas, with good results.

Experiments with fine screenings showed that pressing was impracticable, but that a salable fertilizer could be produced from them by pressure cooking, and that an inert product resulted from their biological digestion.

Sink Hole Topography Study for Sewage Disposal. J. E. Lamar. *Engineering News-Record*, vol 99, No. 16, October 20, 1927, pp. 642–643. (Abstract by A. H. Wieters.)

A proposal by the city of Alton, Illinois, to dispose of sewage from a rapidly growing subdivision into a sink hole resulted in a study by the Illinois Geological Survey and the Illinois Department of Health. The question raised was whether the sewage thus disposed of would enter the Mississippi River directly above the Alton Water Works intake. The study disclosed that it would.

Fluorescein was introduced into the stream entering the sink hole and by the following morning green color persisted for two hundred feet in the Mississippi River below the mouth of the subterranean channel.

The article describes in detail the geology of the area.

Interstate Control of Stream Pollution. John E. Monger. *Nation's Health*, Vol. 9, No. 8, August 15, 1927, pp. 16–18 and 68. (Abstract by Paul S. Fox.)

The writer believes that the State health department is the logical organization to exercise control of stream pollution. Citation is made of the cooperation of the nine State health departments which are interested in the control of the Ohio River system. Brief descriptions of the methods employed by some of the industries affected to solve their own problems are given. "The possibilities of cooperative action among the States, and particularly the health departments of the States, are apparently unlimited; and with the development of a conscience by the States, the stream pollution problems as affecting one another may be solved without the intervention of Federal agencies."

Sanitary Construction and Arrangement of Milk Pasteurizing Plants. C. A. Holmquist. *American Journal of Public Health*, vol. 17, No. 11, November, 1927, pp. 1121–1124. (Abstract by H. D. Cashmore.)

The knowledge that Pasteurized milk is safe and keeps well has led to an enormous consumption of this ideal food and requires that much attention be given to the location, construction, and maintenance of Pasteurizing plants as well as efficiency of operation.

The selection of a site for the plant is usually based on economic considerations, but sanitary considerations can not be ignored. Nearness to transportation and center of distribution are important from an economic standpoint, but freedom from dust and traffic congestion are important also. Location as to barns and other fly-breeding places is discussed briefly in this article.

Under the heading of construction of building, the following points are discussed: (1) Equipment; (2) lavatories and toilets; (3) offices, boiler rooms, etc.; (4) light and ventilation; (5) floors, walls, and ceilings.

A complete but brief summary covering the important points of the article appears at the end.

Improvements in Lime-Soda Water Softening Methods at Columbus, Ohio. Chas. P. Hoover. Sixth Annual Report of Ohio Conference on Water Purification, 1926, pp. 63–71. (Abstract by R. E. Thompson.)

The theoretical limit for softening by lime-soda process is 2 g. per g., and this limit can not be reached in practice unless heat is employed or excess chemicals are used. This is believed to be due to the formation of complex basic carbonates. A chart is given showing theoretical and actual reduction in alkalinity and incrustants by addition of soda ash in increasing quantities to a magnesium water. Efficiency may be increased by split treatment, proper agitation, and by use of a coagulant. At Columbus it has been found that hardness can be reduced from 318 to less than 60 p. p. m. without the use of excess chemicals by adding 5 g. per g. of alum. Experiments are being conducted on zeolite softening. While it is cheaper to remove carbonate hardness with lime than by base exchange, the cost of removing noncarbonate hardness by the latter method is only one-half that of soda ash treatment. It is planned to replace sand in one of the filters with zeolite sand for experimental purposes. It is believed that hardness can be reduced to 160 p. p. m. with lime, and that to produce water of 80 p. p. m. it will be necessary further to treat only one-half of total in zeolite filters.

Comfort Stations are not Necessarily Nuisances as to Owners of Adjacent Property. Anon. *American City*, vol. 38, No. 1, January, 1928, p. 181–182.

Refusing to abate a municipal comfort station upon the plea that it per se constituted a nuisance against near-by property owners, the Washington Supreme Court said in the case of Zey *v.* Town of Long Beach (258 Pacific Reporter, 492):

"A comfort station is not a nuisance per se and may or may not be such in fact, depending upon the attendant facts and circumstances * * *. Before it can be held that the comfort station constituted a nuisance, it must be found that it interfered with the comfortable enjoyment of the appellants in their life and use of their property * * *. There is no direct evidence that the rental value of the rooms or cottages was impaired by the presence of the comfort station or that the value of the property was reduced. It is undoubtedly true that the presence of the comfort station directly to the west and immediately in front of the residence of the appellants is not a thing to be desired. It would offend against the esthetic sense, but this would not be sufficient to make it a nuisance."

Public Health Engineering in Australia. F. F. Longley. *American Journal of Public Health*, vol. 17, No. 3, March, 1927, pp 228–232. (Abstract by H. D. Cashmore.)

Through the influence of the International Health Board some few years ago, sanitary engineering was given a foothold in Australia; and the interest shown by the Government and the views already taken on this work have made it possible firmly to establish sanitary engineering as a public health activity.

Until this time no engineers were included in the health organisation, as sanitary engineering work under state health officers was considered unnecessary. The first step was to adopt a policy in regard to who should be the authority to enforce this work, State or Commonwealth, and State rights won out. The next step was the selling of public health engineering to the people, and a conference of all State medical officers was held to plan the future work. Out of this came *Health*, the vehicle by which the advertising was carried on.

One of the chief sanitary problems was the installation of sewerage systems in the larger towns. In places where they were not practicable, the disposal of night soil was studied. In this connection there was outlined a definite set of problems to be studied and solved.

Knowing that the International Health Board was there for only a limited time, an engineer of some experience was appointed to take charge of this work. He was sent to America and Europe to study the latest ideas on this work. Based upon the activity and interest shown by the people, a five-year program was presented at a second meeting of the health officers assembled to discuss public health.

Sanitary Problems in a Colliery District. W. A. Murphy. *Journal of State Medicine*, vol. 35, No. 9, September, 1927, pp. 545–549. (Abstract by L. M. Fisher.)

Colliery towns are usually built in narrow ravines where there is barely room for river, railroad, and highway. The stream is polluted with coal washings and surface wash from the villages. The water supply frequently obtained from surface sources is often contaminated.

Subsidence due to mining operations damages the houses so that many are made uninhabitable. The pneumonia rate among the workers is high. Pit-head baths should be provided. Smoke-abatement measures should be instituted. The sanitary problems in general are peculiar to collieries.

DEATHS DURING WEEK ENDED FEBRUARY 18, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended February 18, 1928, and corresponding week of 1927. (From the Weekly Health Index, February 23, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended Feb. 18, 1928	Corresponding week, 1927
Policies in force	69, 956, 655	66, 767, 638
Number of death claims	12, 983	14, 209
Death claims per 1,000 policies in force, annual rate	9. 7	11. 1

Deaths from all causes in certain large cities of the United States during the week ended February 18, 1928, infant mortality, annual death rate, and comparison with corresponding week of 1927. (From the Weekly Health Index, February 23, 1928, issued by the Bureau of the Census, Department of Commerce)

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Data for 68 cities.
[4] Deaths for week ended Friday, Feb. 17, 1928.
[5] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

PLAGUE-PREVENTION WORK IN THE UNITED STATES

Seattle, Wash.—The reports of rat-trapping operations of the United States Quarantine Station at Seattle for the months of December, 1927, and January, 1928, show a total of 2,199 rodents taken and 1,055 examined. None were reported plague-infected.

Los Angeles, Calif.—The rodent division of the Los Angeles Board of Health reports 7,888 rodents collected, and 4,822 examined during the nine weeks from December 4, 1927 to February 4, 1928. None were found plague-infected.

San Francisco Calif.—The weekly reports of plague-suppressive measures in California during the six weeks November 27, 1927, to January 7, 1928, show a total of 4,190 rodents received and 3,470 examined. No plague infection was reported during this period. The last case of human plague occurred in July, 1927, in Contra Costa County.

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 100 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 31,100,000. The estimated population of the 94 cities reporting deaths is more than 30,400,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended February 11, 1928, and February 12, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
41 States	2,021	1,863	
100 cities	999	1,049	1,025
Measles:			
40 States	15,002	12,047

94 cities	1,073	980	
Smallpox:			
94 cities	0	0	

City reports for week ended February 11, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during non-epidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population, July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

[1] Typhus fever: 1 case at Savannah, Ga.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended February 11, 1928, compared with those for a like period ended February 12, 1927. The population figures used in computing the rates are approximate estimates as of

July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, January 8 to February 11, 1928—Annual rates per 100,000 population, compared with rates for the corresponding period of 1927 [1]

	Week ended—

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended January 28, 1928.—The following report for the week ended January 28, 1928, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Aden Protectorate.—Aden.
India.—Bassein, Bombay, Calcutta, Rangoon
Ceylon.—Colombo.
Siam.—Bangkok.

CHOLERA

India.—Calcutta, Madras, Negapatam.
Dutch East Indies.—Semarang.
French Indo-China.—Saigon and Cholon.
Siam.—Bangkok.

SMALLPOX

India.—Bombay, Calcutta, Madras, Negapatam, Rangoon, Tuticorin, Vizagapatam.
French India.—Pondicherry.
Dutch East Indies.- Banjermasin, Belawan-Deli.
China.—Hong Kong, Shanghai
Kwantung.—Dairen.
Manchuria.—Changchun, Mukden.

Returns for the week ended January 28 were not received from Samarinda, Dutch East Indies, Canton, China, or Vladivostok, Union of Socialist Soviet Republics.

CANADA

Provinces—Communicable diseases—Week ended February 11, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended February 11, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever				1				1
Influenza	15			3		1		19
Lethargic encephalitis				1		1		2
Poliomyelitis							1	1
Smallpox				51		34	6	91
Typhoid fever		1	15	7			12	35

Quebec—Communicable diseases—Week ended February 11, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended February 11, 1928, as follows:

Disease	Cases	Disease	Cases
Chicken pox	24	Scarlet fever	96
Diphtheria	94	Smallpox	8
German measles	4	Tuberculosis	46
Influenza	5	Typhoid fever	15
Measles	144	Whooping cough	8

CZECHOSLOVAKIA

Communicable diseases—September 1 to December 31, 1927.—During September, October, November, and December, 1927, communicable diseases were reported in Czechoslovakia as follows:

	September		October		November		December	
	Cases	Deaths	Cases	Deaths	Cases	Deaths	Cases	Deaths
Anthrax	13	2	3		4	1	8	
Cerebrospinal meningitis	4	1	11	3	8	5	13	4
Diphtheria	682	42	887	55	1,062	89	1,045	107
Dysentery	166	19	77	1	61	15	7	1
Malaria	83		83		6		6	
Paratyphoid fever	21		8	1	7		4	1

Trachoma	179		219		247		213	
Typhoid fever	1,083	61	1,126	65	1,006	82	682	45
Typhus fever	6		1				6	

GREAT BRITAIN

England and Wales—Vital statistics, 1927.—The following item is taken from The Lancet of January 21, 1928:

The Registrar General of England and Wales has issued a provisional statement of the figures for birth rate, death rate, and infantile mortality during the year 1927.

	Birth rate	Death rate	Infant mortality rate
England and Wales	16.7	12.3	69
107 county boroughs and great towns including London	17.2	12.3	71
155 smaller towns	16.5	11.4	68
London	16.1	11.9	59

The smaller towns are those with an estimated population in 1921 of 20,000–50,000. The death rate for England and Wales relates to the whole population, but that for London and the two groups of towns to the civil population only. Birth rates and death rates are per 1,000 population; infant mortality rate per 1,000 births.

The registrar general remarks that the birth rate is 1.1 per 1,000 below that of 1926, and is the lowest rate recorded since the establishment of civil registration. The death rate is 0.7 per 1,000 above that of 1926; the excess being due to the high mortality of the first and fourth quarters of the year. The infant mortality rate is equal to that of 1923, the lowest on record; the rate in 1926 was 70 per 1,000 births. These provisional figures, which are not likely to require substantial modification, have been issued for the information of medical officers of health.

GUATEMALA

Plantation sanitary campaign.—According to information received under date of January 20, 1928, the health department of Guatemala has issued regulations relative to a sanitation campaign for improved health conditions on the plantations of the Republic. The operation of the proposed campaign includes: Requirement to maintain medicine chest with equipment for first-aid treatment; employment of a community plantation physician who shall be charged with the duty of regular visits and oversight of prophylactic and hygienic conditions; vaccination against smallpox and typhoid fever required for admission to plantations; maintenance of sanitary privy system; protection of dwellings against mosquitoes; adequate ventilation and removal of sleeping quarters from vicinity of kitchens; requirement that plantation owners keep records of cases of sickness among their laborers, with personal history of patients, duration of illness, date of cessation of labor, recovery, death, etc. Penalties for noncompliance with these regulations are provided in the plan of the campaign.

UNION OF SOUTH AFRICA

Plague (*suspect*)—*Orange Free State.*—Information received under date of January 13, 1928, relative to suspect cases of plague which occurred in natives on two farms in Koffiefontein District of the Orange Free State, Union of South Africa, and were reported during the two weeks ended December 24, 1927, shows that immediately preceding the onset of the illness the patients had caught by hand a hare which was obviously sick.

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

[1] From July 19 to Dec. 26, 1927, 1,479 cases of cholera were reported in Iraq, with 1,063 deaths, as follows: Amarah Liwa, 261 cases, 205 deaths; Baghdad Liwa, 80 cases, 60 deaths; Basra Liwa, 421 cases, 330 deaths; Diwaniah Liwa, 122 cases, 72 deaths; Diyalah Liwa, 1 case, 1 death; Dulaim Liwa, 100 cases, 69 deaths; Hillah Liwa, 105 cases, 71 deaths, Kerbalah Liwa, 79 cases, 60 deaths; Kut Liwa, 66 cases, 44 deaths; Muntafiq Liwa, 244 cases, 151 deaths. The report of 29 cases of cholera with 18 deaths at Baghdad during the week ended July 30, 1927, which appeared in the PUBLIC HEALTH REPORTS Sept. 23, 1927, and in subsequent issues, was erroneous. The director of public health of Iraq states that cholera did not appear at Baghdad in 1927 until Oct. 20.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

PREVALENCE OF DISEASE

PUBLIC HEALTH REPORTS

VOL. 43 MARCH 9, 1928 NO. 10

MONTHLY REVIEW OF WORLD PREVALENCE OF COMMUNICABLE DISEASES [1]

United States, January 1–February 11, 1928

Health conditions during the first five weeks of 1928 were exceptionally favorable. The mortality in 66 large cities during these weeks was 13.7 per 1,000 population (annual basis), as against 14 in the corresponding weeks of 1927, which was also an unusually good health year. Not since 1921 has the January mortality in large cities—and conditions in these cities may be considered a fair index of conditions in the country as a whole—been as low as in the current year. The seasonal maximum occurs, as a rule, toward the end of February or in March, so that although the present outlook would seem to indicate a generally healthful winter, there may be some increase in mortality in the next few weeks.

Influenza.—Influenza had shown only a normal seasonal increase in most parts of the country up to the end of January. Cases of this disease, which is not very well reported, were even less numerous than in January, 1927, except in a few Southern States. The total number of deaths from influenza and pneumonia, which are a better index of the prevalence of any serious respiratory affection, but which are available for less recent date than the reported cases, gave approximately the same mortality rate for 95 cities during December and the first three weeks of January as a year ago. For the cities in the northern and western sections the average mortality from these causes in the first three weeks of the year was about the same as or lower than a year ago, but in the South Atlantic, East South Central, and, especially, in West South Central States the average mortality in the cities was somewhat higher. There was no indication, however, of any epidemic of respiratory diseases.

Smallpox.—Smallpox has been somewhat more prevalent in recent weeks than in the corresponding weeks of the preceding two years.

[1] From the Office of Statistical Investigations, United States Public Health Service.

There is no indication that any of the outbreaks have been virulent in type. The cases reported by 42 States were as follows:

Week ended [1]—	Corresponding week of—		
	1926	1927	1928
Jan. 7	810	781	815
Jan 14	894	853	1,274
Jan. 21	977	908	1,151
Jan 28	846	983	1,125
Feb 4	1,021	1,017	1,2[illegible]
Feb. 11	1,081	839	1,068

[1] Dates are for the year 1928.

The increase in smallpox cases has occurred chiefly in the West Central and Mountain States, particularly in Kansas, Iowa, and Oklahoma. Marked improvement in the smallpox situation is indicated for most Southern States. In Georgia no cases had been reported in the first five weeks of the current year, as against 385 in January, 1927; in Florida 22 cases had been reported in the same period, as compared with 169 in January a year ago; in Alabama 25 cases had been reported, as compared with 241. In North Carolina smallpox has been prevalent for several years, and in the current year the number of cases has increased markedly; 590 cases were reported in the first five weeks, as against 276 in January, 1927, and 156 in January, 1926. An unusual outbreak of smallpox in Connecticut is indicated; 120 cases were reported up to February 4, although the State has been practically free from this disease for several years.

Scarlet fever.—Scarlet fever has shown only the normal seasonal increase in incidence. Up to February 4 there had been fewer cases reported than during the corresponding season one year ago, and approximately the same as the number reported two years ago. The decline as compared with last winter is very general, only three States having reported more cases than in the same period a year ago. The States reporting more cases in the present year are Nebraska, Iowa, and Rhode Island, but in none of them has there been any unusual epidemic prevalence. The seasonal maximum usually is not passed until the end of February or early in March, but there is nothing to indicate that any marked increase should be expected in the present year.

Diphtheria.—The number of diphtheria cases reported during January by 41 States corresponded very closely with the number reported in the same month a year ago; in both years the January incidence was slightly higher than in January, 1926. In most States the number of cases reported in the early weeks of the current year did not differ significantly from the number reported last year. States

showing a somewhat higher incidence in the present year include Connecticut, District of Columbia, Illinois, Kansas, Louisiana, New Jersey, New York, Pennsylvania, and Texas.

Measles.—Measles cases increased rapidly during January; 41 States, including the District of Columbia, reported 6,674 cases in the week ended January 7, but these same States reported 12,730 cases in the week ended February 4. The incidence in the present year has been slightly above that a year ago, but about the same as that of two years ago. This disease is epidemic every second or third year in most localities and, therefore, over the country at large in any year it may be expected to be epidemic in a certain number of States. The seasonal maximum probably will not be reached until late in the spring; present indications are that it will be more epidemic in the current year than last year, but it is too early to tell whether or not the incidence will be as high as in 1926.

Poliomyelitis.—New cases of poliomyelitis reported during January and the early part of February continued above the level of reported cases for the corresponding period of the preceding two years, but the number was gradually declining. The largest number of cases was reported in California (17 cases in the week ended February 4); other States reported only sporadic cases.

Typhoid fever.—Typhoid fever was more prevalent than a year ago in the South and Central States and less prevalent in other sections of the country, but the incidence is low at this season of the year.

Foreign Countries[2]

The mortality rates in a large number of European towns showed only a slight seasonal increase in November and December. There was no indication that the mortality was disturbed by any serious epidemic situation. In a few cities for which data for December were complete the increase was marked but not unusual. For example, in 16 Scottish towns the death rate in the four weeks ended December 31 was 18.6 per 1,000 (annual basis), as against 14.7 in the preceding four weeks; in Dublin, the death rate was 18.1, as compared with 14.6 in the preceding four weeks; the average death rate in 107 English towns for four weeks in December was 14.1, as against 11.3 in the preceding four weeks.

The following information on the prevalence of specific diseases has been taken from the League of Nations' Monthly Epidemiological Report.

Cholera.—The cholera epidemic in Iraq came to an end in December, after lasting five months. During this period 1,479 cases and 1,063 deaths were reported. In the previous epidemic in 1923 there

[2] Data from Monthly Epidemiological Report of the Health Section of the League of Nations' Secretariat, Jan. 15, 1928, supplemented by information published in the Public Health Reports.

were 1,640 cases and 1,097 deaths. More cases occurred in the districts along the Euphrates River in the recent epidemic than in 1923, but the incidence in Basrah and Abadan was much lower, and the city of Baghdad had almost complete immunity in 1927, with only 7 cases reported.

In India cholera was abnormally prevalent in November for the time of year The disease was particularly epidemic in Bengal and increased also in Assam, Bihar, and Orissa, and in Madras Presidency. The number of deaths reported in the various provinces is shown in the accompanying table. The serious epidemics in Bombay Presidency, Hyderabad, and the Central Provinces, which reached their maximum in August and September, had nearly come to an end in November.

In French Indo-China cholera cases have decreased rapidly since July. In Tonkin, only 3 cases occurred in the last quarter of 1927. Laos was free from cholera from November 10 to the end of December. In December, Annam reported 18 cases, Cambodia 72 cases, and Cochin-China 113 cases.

Cholera infection in ports of the Far East had decreased very markedly at the close of 1927. In the first two weeks of January, 1928, Calcutta reported 43 deaths, Bangkok (16 cases), Singapore 5 cases, Saigon 3 cases, and Rangoon and Moulmein each reported 1 case.

Cholera deaths reported in the Provinces of India from August 14 to December 3, 1926 and 1927

Plague.—The plague incidence in Egypt in 1927 was the lowest on record since the introduction of plague into Egypt in 1899; a total of 79 cases was reported. Twelve cases which occurred at Alexandria between the middle of November and the end of December were the only cases reported in 1927 after September 4.

No case of plague had been reported in Tunis since last July, and none in Algeria since November 17. Greece reported two cases on the island of Mytilene early in December and one case at Piræus on January 3.

Three plague cases occurred at Las Palmas, in the Canary Islands, on December 15. Early in January there were two further cases, and a third case on January 15. One case was reported at Santa Cruz de Teneriffe on January 12.

No plague case has been reported in Senegal since the first week in December. This is the usual quiescent period for plague in Senegal, which lasts until March. In Nigeria the plague situation is much more favorable than it was in the three preceding years. Seventeen cases were reported at Lagos and 3 at Ijebu during the four weeks ended December 31; 67 cases were reported in these two localities in December, 1926. There were 7 cases at Lagos during the first two weeks of January, 1928.

There seems to be a halt in the annual increase of plague in Madagascar, which has been continuous since the introduction of the disease in 1921. The monthly number of cases reported has been lower than in the corresponding month of the preceding year for each month since August, 1927. During the month ended December 15, 1927, there were 243 cases, as compared with 314 during the corresponding period of the preceding year. The maximum prevalence usually occurs between December and February.

Plague was more prevalent in Uganda in 1927 than in any year since 1921; 1,704 deaths from plague were reported from the beginning of the year up to November 26. During the previous five years the reported annual plague mortality has ranged between 535 (in 1924) and 1,608 (in 1926). The maximum prevalence occurred in August. Plague has diminished in Kenya since 1925.

The plague outlook in India remained favorable in November. Returns for the Punjab are very low in comparison with previous years. In Bihar and Orissa, which was practically free from plague from June to the end of October, 51 cases were reported during four weeks ended December 3. The incidence of plague was likewise lower than in previous years in the United Provinces up to the middle of November, since which time there has been an increase which is somewhat rapid for the season. There was as usual an increased prevalence of plague in November in the State of Hyderabad and in the Central Provinces. The normal seasonal maxima of plague in the Bombay and Madras Presidencies (excluding the city of Bombay) as well as in Mysore are passed. Plague was rapidly decreasing in the Madras Presidency during the second half of November, except in the district of Madura, in the extreme south,

where the disease is markedly more prevalent than in the three preceding years.

Bubonic plague appeared in Aden on January 9, 1928, on which day 19 cases were reported. Since the outbreak of 1917, indigenous plague had not been reported from Aden until the present outbreak.

Yellow fever.—The yellow-fever situation on the Guinea coast has considerably improved. Only 6 cases were reported at Dakar in December; Senegal was free. The last case occurred during the week ended December 27, and Dakar, as well as Senegal, was declared free from yellow fever on January 6, 1928.

No case of yellow fever has been reported in the Gold Coast Colony since October. The number of cases reported during the year has been considerably higher, however, than during any year since the reappearance of yellow fever in this area. There was 1 case of yellow fever during the last week of December at Abidjan on the Ivory Coast, where the disease had not been reported since August. No case has been reported in Dahomey since November 21, nor in Nigeria since September.

An outbreak of yellow fever occurred at Matadi, in the Belgian Congo, during the week ended December 23; 3 cases (2 fatal) were reported. An additional fatal case occurred on a steamer at Boma. A few suspected cases have also been isolated.

Smallpox.—Smallpox has been less prevalent in England and Wales than it was last winter. During the four weeks ended January 7, 1928, there were 989 cases, as compared with 1,371 cases during the corresponding period of the preceding year There was, however, a marked increase in the number of cases during the second week of January 1928, when 398 cases were reported. There appears also to have been some spread of the disease, as cases were reported in 17 counties during that week. The large majority occurred, however, in Durham and Yorkshire in the north and in Monmouthshire and Glamorganshire in South Wales

In Spain, where the incidence had been much lower than in previous years, a new increase occurred in the autumn; 18 deaths were attributed to smallpox in September and 34 in October, as compared with only 3 during each of the corresponding months of the preceding year.

The serious epidemic in Algeria began to decrease in December. Only 9 cases were reported during the first week of January, 1928—all in the department of Oran. The total number of cases reported in Algeria in 1927 was 4,305, as compared with 2,473 in 1926, 1,747 in 1925, 483 in 1924, and 141 in 1923. Smallpox incidence, on the contrary, was comparatively low in December in both Tunis and Egypt. It spread in Morocco, where the number of cases increased from 51 in September to 401 in December.

The incidence of smallpox in India increased as usual in November, but was lower than in the preceding year; 1,556 cases were reported during the week ended December 3, as compared with 2,423 during the corresponding week of 1926.

Enteric fever.—Enteric fever was more prevalent in England and Wales in 1927 than in either 1925 or 1926; and the seasonal maximum was not reached until the latter part of November, which is unusually late. In 1925 the maximum occurred in August, and in 1926 it occurred in September.

The maximum incidence occurred earlier in 1927 than in 1926 in France, Italy, Hungary, and in the Kingdom of the Serbs, Croats, and Slovenes. In Italy the incidence in September was much in excess of that of the preceding years, but in October the cases were fewer than in the corresponding month of 1926.

In Poland, Czechoslovakia, and Belgium the incidence of enteric fever was higher in September, October, and November of 1927 than it had been in the corresponding period of 1926.

Enteric fever was considerably more prevalent in Egypt during the late summer months than it had been in 1925 or 1926.

In Japan the number of cases of enteric fever reported in the latter half of 1927 was slightly higher than in the same period of 1926, but in the first quarter of 1927 the cases were much fewer.

Influenza.—No indication of the approach of any serious influenza epidemic in European countries was noted in either the notifiable disease reports or the mortality statistics for large towns which had been received by the health section of the League of Nations up to the middle of January.

The number of deaths attributed to influenza in large towns of England and Wales increased gradually from the beginning of December, but the increase was slow and there were none of those sudden jumps which usually announce the onset of an epidemic. The influenza deaths in 107 towns increased from 63 during the week ended December 3 to 155 during the week ended January 7.

The seasonal increase, in December, of deaths attributed to influenza in 49 large towns of Germany was also very slow—189 deaths during the four weeks ended December 31 as compared with 116 deaths during the preceding four weeks.

Deaths from influenza in towns of Scotland and northern Ireland were more numerous during December and the first half of January than last winter. In 16 Scottish towns 63 deaths were attributed to influenza during the four weeks ended January 14, 1928, as compared with 47 deaths during the corresponding period of last year.

In nine towns of northern Ireland there were 31 deaths from influenza during these four weeks, as compared with 18 deaths during the corresponding period of 1926–27.

Nine deaths from influenza were reported in 11 towns of the Irish Free State during the four weeks ended January 14, 1928, the same number as reported during the corresponding period of the preceding winter.

There was practically no increase from November to December in influenza cases notified in Denmark or Finland.

In France information is available for the cities of Paris and Lyons. In Paris 23 deaths from influenza were reported in December, as compared with 332 deaths during the corresponding month of 1926. At Lyons there were 7 deaths from influenza in December, as compared with 19 in December, 1926.

Statistics for various other large towns show no high prevalence of influenza during the first week of January.

Encephalitis lethargica.—No noteworthy outbreak of this disease was reported in December. The number of cases reported in England and Wales increased from 106 during the four weeks ended December 3 to 134 during the four weeks ended December 31, but both returns were lower than the corresponding figures for the preceding three years. Since the maximum was passed in 1924 there has been a steady decrease of the annual number of cases of encephalitis lethargica in England and Wales and in Scotland. The decrease has been continuous in Sweden and in Switzerland since 1923. The highest annual total was reported in Switzerland in 1920 and in Sweden in 1921.

Cases of encephalitis lethargica reported in various European countries, 1923–1927

Country	1923	1924	1925	1926	1927
England and Wales	1,025	5,039	2,636	2,367	1,617
Scotland (towns)	-------	631	206	194	130

Switzerland	203	87	71	36	22
Italy	255	617	681	450	[1] 246
Czechoslovakia	366	97	189	54	[2] 68
U. S. S. R.	920	1,990	2,093	2,272	[3] 1,045

[1] 10 months. [2] 11 months [3] 9 months.

Poliomyelitis.—The poliomyelitis outbreaks that occurred in Europe during the autumn of 1927 have decreased rapidly during the last two months. In Germany, where a weekly maximum of 240 cases had been reached in September, there was an average of 20 cases a week during the last three weeks of 1927. The total number of cases reported during the year was 2,742, and the number of deaths attributed to poliomyelitis was 296, as compared with 1,614 cases and 171 deaths during the preceding year and 386 cases in 1925.

In Austria 145 cases were reported in 1927, in comparison with 36 cases the preceding year.

The total number of cases reported was lower in 1927 than in 1926 in England and Wales, in France, and in Denmark. In Sweden the number of cases reported in 1927 was slightly higher than in 1926, but much lower than in the preceding two years.

The incidence was above normal also in Canada, where 309 cases were reported in November and 164 in October, as compared with 26 and 35, respectively, during the corresponding month of the preceding year.

Diphtheria.—Diphtheria was more prevalent everywhere in Europe during the last quarter of 1927 than during the corresponding period of the two or three preceding years, with the sole exception of the Union of Socialist Soviet Republic, where the high prevalence during the two preceding years has remained about the same. The increase was general in all countries from the far north to the extreme south of Europe, and was noted also in countries of the Mediterranean coast of Africa. It did not occur in the form of sudden epidemics, but consisted in a slow and mostly moderate increase of the incidence, beginning in late summer or in autumn, which reached its maximum in most countries in November.

The prevalence in the fourth quarter of the last three years is shown below for England, Germany, and France.

	England and Wales	Germany	France
Fourth quarter 1925	13,771	8,842	2,849
Fourth quarter 1926	14,653	8,684	3,708
Fourth quarter 1927	18,160	10,646	4,309

Scarlet fever.—Scarlet fever, in contrast with diphtheria, shows no general movement common to all European countries. There was a decreased prevalence in the fourth quarter of 1927 in most European countries as compared with the preceding year, but the incidence increased, on the other hand, in England and Wales, Norway, Denmark, Germany, Austria, Italy, the Kingdom of the Serbs, Croats, and Slovenes, and Bulgaria. The increase was considerable in Germany, where 29,934 cases were reported during the fourth quarter of 1927, as compared with 21,816 and 11,793, respectively, during the corresponding periods of 1926 and 1925, and in the Kingdom of the Serbs, Croats, and Slovenes, where the number of cases reported during the fourth quarter of the year increased from 2,917 in 1925 and 1,828 in 1926 to 4,883 in 1927. In most countries the maximum prevalence was reached in October, but in some not until November.

THE HEALTH RECORD OF UNIVERSITY STUDENTS AS RELATED TO TONSILLECTOMY

By Warren E. Forsythe, M. D., Dr. P. H., *Professor of Hygiene and Public Health, University of Michigan*

The improvements so frequently seen to follow well-advised tonsillectomy seem to justify the supposition that a significant difference might be demonstrated between groups of persons having, and those not having had the operation. In an attempt at studying that question, the experience of the University of Michigan Health Service has been drawn upon. For several years the department has examined entering students, cared for their subsequent illness, and collected considerable data.

In an effort at evaluation of the tonsillectomy, the records of two classes have been analyzed. Students entering without tonsils have been compared with those entering with tonsils in place. The accompanying tabulations give comparisons on many points for the two groups.

Table 1.—*Comparison of health items in men students who have and have not had tonsillectomy in the class of 1926—entrance year, fall of 1922*

DISCUSSION

There seems to be little if any significant difference in these data relative to the health of students who came to the University of Michigan with or without having had the operation of tonsillectomy. The data given are for the findings at the entrance examination and during subsequent attention to health through the period of university residence. There is a suggestion of advantage to the tonsillectomized group in general appearance of nutrition and general health grade. The most significant differences seem to indicate that those students with their tonsils in have less trouble with acute upper respiratory infections, but they have more cervical adenopathy.

It must be assumed that the tonsillectomies were done on people who were having trouble and were particularly subject to illness. Such being the case, the operations must have enabled that group to overcome the handicap and enjoy health equal to other students. Case data relative to conditions before and after tonsillectomy in the same persons will probably give the best evaluation of the operation. The need for conservatism in tonsillectomy was recently voiced by Canfield.[1]

PUBLIC HEALTH ENGINEERING ABSTRACTS

Indianapolis Keeps Profit in Garbage. Eugene M. Reid. *The American City*, vol. 37, No. 6, December, 1927, pp. 753-757. (Abstract by J. B. Harrington.)

Under the supervision of E. W. McCullough, consulting engineer, and the board of commissioners, experiments were begun in 1922 to determine a satisfactory method of garbage reduction. The new plant constructed in Indianapolis at a cost of $460,000 contains modern equipment for extracting all salable products from the refuse

Details of the collection trailers, McCullough separators, digesting tanks, and screens are given. Tests have shown that 5.43 tons of green garbage produce 1 ton of crude tankage consisting of approximately 14 per cent of coarse rubbish, 34 per cent fine rubbish, and 52 per cent of feed tankage. Approximately 40 pounds of grease per 1 ton of garbage also are obtained. Grease is worth from 5 to 7 cents per pound and fertilizer filler about $4.50 per ton.

During the three months, June 1 to August 31, the net profit, deducting capital charges, amounted to $15,195.94.

Refuse: Its Storage, Collection, and Disposal. T. Douglas. *The Surveyor*, vol. 72, No. 1860, September 16, 1927, pp. 251-252. (Abstract by C. C. Ruchhoft.)

A variety of articles are used for the storage of refuse in England, but a uniformity in receptacles is desirable. A portable dust bin is recommended as the best possible means of storage for domestic refuse.

The cost of collection varies from $0.75 to $3.75 per ton, and there is room for improvement and reduction in cost. The tendency in England has been toward the replacement of horses by automobiles for collection. The absence of alleys and the long carrying distances down terraces and sometimes through dwellings increase time and cost of collection. It was found that two vehicles working in conjunction in districts supplied with portable dust bins have given the most economical service.

The disposal of refuse without offense to nose or eye is a difficult task and requires that the cleansing departments be equipped, organized, and controlled in an efficient manner. Due to the varying character of the refuse, various methods of disposal are employed, each claiming efficiency and economy. The efficiency of a method for a community can be estimated only after a study of the local conditions.

Odors from Rendering Offal. Robert D. MacLaurin. *American Journal of Public Health*, vol. 17, No. 10, October, 1927, p. 1026. (Abstract by H. N. Old.)

Brief description is given in this article of the two methods of fat recovery from offal—the wet method, which involves cooking the material with steam under pressure, and the dry method, which consists in cooking in a "melter," in which the protein material is cooked in its own fat.

[1] Annals of Clinical Medicine, vol IV, No. 12, June, 1926.

The dry method is gradually replacing the wet method; and from the point of view of odors it is simpler, cheaper to operate, and requires less care, the only odor control equipment required being a water condenser to condense the steam and volatile gases from the cooking operation.

It is stated that the principal consideration in control of odors from offal rendering is that of processing the material in a fresh condition, as putrefaction will be found the usual cause of excessive odor in rendering. The question of satisfactory odor control is essentially one of efficient plant management in the use of either the wet or dry system, and the conclusion is reached that the watchword for odorless rendering of offal is "prevention."

Oyster Storage. John E. Bacon. *Public Health News*, vol. 13, No. 1, December, 1927, pp. 16–23. (Abstract by Harriet S. Ryan.)

This is a report of the investigation made of the oyster industry at Maurice River, which furnishes employment for about 3,500 men. The prosperity of the industry was threatened by a ruling of the Federal Department of Agriculture which prohibited interstate shipment of oysters stored in waters of less salt content than that in which they were grown. Oysters taken from the south Jersey beds contain quantities of objectionable silt, which is removed by allowing the oysters to cleanse themselves in "storage floats." In order that these floats may be protected from storms and not be a menace to navigation, they are placed near the mouths of rivers or creeks, which, on account of the lower salinity of such waters, results in the incorporation of some additional waters in shellfish. This was a violation of the pure food and drug law, and the problem before the oystermen and the State department of health was to find an uncontaminated storage area sufficiently high in salinity to prevent the oyster from taking on "added water." An investigation was made of the area at the mouth of the Maurice River to determine the effect of storage upon oysters placed in these waters.

A concise account is given of the operations and the results of the investigation, together with illustrative pictures, a map showing location of the floats used in this study, and a table outlining the experiments.

The investigation showed that salt oysters from Delaware Bay can be stored for cleansing purposes in the waters of Greenbank Reach, Maurice River, and removed from the "float" during the first of ebb tide and not contain an excessive amount of "added water." The United States Department of Agriculture now acknowledges the necessity of storage for purposes of cleansing and improving oysters and approves the waters at the mouth of the Maurice River for this purpose, provided the shellfish are removed from the storage float during certain stages of the tide so as to result in the incorporation of the least added water. This period of the tide is between one hour before high water and three hours before ebb tide.

Use of Returned Sludge Speeds up Water Softening Reactions. Anon. *Engineering News-Record*, vol. 99, No. 19, November 10, 1927, p. 748. (Abstract by D. E. Kepner.)

According to A. W. Bull, in a paper presented before the Southwestern Water Works Association in October, 1927, laboratory tests at Columbus and Pittsburgh showed that the use of returned sludge hastened water softening reactions considerably.

At Columbus, 19 hours' agitation was required, without the use of returned sludge, to reduce the soap hardness of the water to 66 p. p. m., while the same reduction was accomplished in two hours with the use of 50 cubic centimeters of returned sludge per gallon, and in one hour with 100 cubic centimeters of sludge per gallon, employing 11 grains of lime and 11 grains of soda ash per gallon, and a temperature of 17° C., in each case. The final alkalinity and causticity of the water were not greater when using the sludge than when not using it. Best results were secured with a sludge concentration of 15,000 p. p. m. (about 60 cubic centimeters per gallon).

At Pittsburgh, with water unusually high in $MgSO_4$, a sludge concentration of 7,100 p. p. m. produced good results. The water was apparently softened as easily at 0° C. as at 10° C. with the sludge and in both cases better than could have been done at 30° C. without the sludge. A clearer effluent is also claimed to result from the use of returned sludge.

Emergency Ventilator in Chlorinating Room. Anon. *Engineering News-Record*, vol. 100, No. 1, January 5, 1928, p. 9. (Abstract by Harriet S. Ryan.) A temporary arrangement had to be devised for feeding chlorine gas into the city water at Albany, N. Y., until a new pipe line could be constructed. The apparatus is located in a room underneath the sidewalk adjoining the main pumping station. When leaks occur in the gas line, the pumping station attendant notifies the man in charge of the apparatus, who makes the repairs, closes the air-tight door of the chlorinating room, and starts, from a switch in the pumping station, the electrically driven blower, which draws air from near the floor of the chlorinating room and discharges it into the outside atmosphere.

Progress Report on Gas-Forming Organism in the Akron Water Supply. C. O. Hostettler. Sixth Annual Report of Ohio Conference on Water Purification, 1926, pp. 85–86. (Abstract by R. E. Thompson.) Additional data are given on gas-forming organism present in Akron supply which ferments lactose broth only after 24 hours' incubation and on effectiveness of lactose broth containing 0.5 per cent lactose peptone bile for its inhibition. Results show that modified broth does not inhibit *B. coli*, but does inhibit organisms giving rise to fermentation after 24 hours' incubation. Use of modified broth hastens obtaining of results and reduces volume of work.

Open Reservoirs for Filtered Water on the Distributing System. Clarence Bahlman. Sixth Annual Report of Ohio Conference on Water Purification, 1926, pp. 86–88. (Abstract by R. E. Thompson.) Explosive appearance of vigorous positive *B. coli* tests in tap samples in Cincinnati was traced to contamination of open filtered water reservoir by manure carried by wind from near-by shrubbery beds. The organisms were very resistant to chlorine, and dosages which had to be resorted to gave rise to many complaints of taste. It was more than two months after first appearance of contamination until a coli-free water was again obtained.

Colombian Water Supplies, if Not Pure, Have Many Uses. David and Muriel Yale. *Water Works Engineering*, vol. 80, No. 25, December 7, 1927, pp. 1740 and 1764. (Abstract by Frank Raab.) In Colombia, in the Andes Mountains, where the villages are built on the mountain sides, the inhabitants secure their water supplies from streams which are located on a higher elevation than the village. The streams are tapped and the water is brought to the village through ditches along which the dwellings are located. These ditches provide garbage disposal, sewage disposal, and, in a few instances, power for lighting. The socially elect build their houses at the higher elevations and thus get the water at its purest; while the peons, or poorer classes, who live at the lower ends of these ditches, take the water with all the pollution which it has gathered. A ditch also carries the water to a public fountain, which is usually located in the center of the village; the peon, however, usually does not bother to walk to the fountain for his drinking supply, but contents himself in taking it from the polluted ditch as it passes his dwelling. Women wash clothes, and children, dogs, pigs, cattle, and mules wade about in the stream before it reaches even the first dwellings. The inhabitants never think of blaming the water supply for sickness or death, which it no doubt causes in many cases.

Carbon Dioxide Treatment at St. Louis Water Works. A. V. Graf. *Engineering News-Record*, vol. 99, No. 16, October 20, 1927, p. 643. (Abstract by A. H. Wieters.)

St. Louis is planning a further refinement in the purification of water by the use of carbon dioxide. Each of the two filter plants will be equipped with carbon dioxide devices consisting of a gas-producing burner, combined washer, scrubber and drier, gas burner, and compressor, or blower.

Softening of the water is limited to partial removal of bicarbonate hardness and only occasionally enough lime is used to render the water caustic. The normal carbonate alkalinity of the settled water varies from 22 to 67 p. p. m., and that of water applied to filters from 2 to 30 p. p. m. This reduction is due to the use of aluminum sulphate as a coagulant. The coating on the filter sand now amounts to 17 per cent of the filtering material, and there have been complaints of clogging of water heaters.

The author states that the use of carbon dioxide is not of as recent origin as most water works men believe. He points out that it was used at Derby, England, in 1892.

Softening Plant with Unusual Features. J. F. Laboon. *Water Works Engineering*, vol. 80, No. 25, December 7, 1927, pp. 1731-1732 and 1748–1751. (Abstract by Frank Raab.)

Fostoria, with a population of about 12,000, has an average daily water consumption of 1,400,000 gallons. It is proposed to soften the water by the lime-soda method. The new plant will have a settling basin equipped with a thickener and having a retention period of 2 hours at a 3,000,000-gallon rate, 4 filters each with a 750,000-gallon daily capacity. The filter gravel bed is 18 inches and the sand bed is 30 inches deep; the mixing tank, which also has a stirring equipment to prevent bottom deposits, has a retention period of 30 minutes at a 3,000,000-gallon rate; the clear wells and the clear water basin have a capacity of 645,000 gallons. A centrifugal sump pump to remove drainage and also to remove sludge from the clarifier, is provided. The wash water tank holds 50,000 gallons. There is a carbonating chamber with scrubbers, driers, and compressors, aerating equipment, office, laboratory, and toilet rooms. A belt conveyor carries the sacks of chemicals to the dry-feed machines. The plant has a sand washer, a central operating table with controls of the Venturi meter, the clear wells and wash water basin and also a telemeter gauge of the stand-pipe tower. Each filter has its operating table with loss of head and rate of flow gauges and hydraulically operated valves. The influent wall is perforated to give perfect distribution. The effluent wall is equipped with adjustable baffle weirs. The chlorine room is equipped with two chlorinators and scales. Two points of chlorine application are provided. The estimated cost of the total improvements is $178,529.

The Proper Methods Respecting Chlorination of Water Supplies. J. Van Benschoten. *Public Health Journal* (Canadian Public Health Association), vol. 18, No. 11, November, 1927, pp. 537-542. (Abstract by H. D. Cashmore.)

A brief history up to the present time of the development of chlorination of water and some figures on the reduction of the typhoid death rate in this country are given. The cycle of a water supply is touched on lightly as well as the relation of water to man and certain diseases. There is included a short discussion of the basic types of chlorinators, dry feed and solution feed, including the the vacuum type, in regard to their application to different conditions of climate and water supply. Points to be considered in the selection of a machine, with stress laid on the importance of including all details of construction and equipment of the system, are given with a view of aiding this important step. In addition to the discussion in regard to a water supply, there are also included a few brief statements relative to the use of chlorine in sewage disposal operations.

DEATHS DURING WEEK ENDED FEBRUARY 25, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended February 25, 1928, and corresponding week of 1927. (From the Weekly Health Index, March 1, 1928, issued by the Bureau of the Census, Department of Commerce)

[4] Deaths for week ended Friday Feb. 24, 1928.

[5] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; and Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

UNITED STATES

CURRENT WEEKLY STATE REPORTS

These reports are preliminary and the figures are subject to change when later returns are received by the State health officers

Reports for Weeks Ended March 5, 1927, and March 3, 1928

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 99 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of more than 31,100,000. The estimated population of the 93 cities reporting deaths is more than 30,450,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended February 18, 1928, and February 19, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
41 States	1,945	2,088	
99 cities	1,052	1,203	1,000
Measles:			
40 States	16,119	14,081

[1] Exclusive of Oklahoma City and Tulsa.

City reports for week ended February 18, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics, It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics, or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during non-epidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended February 18, 1928, compared with those for a like period ended February 19, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below.

Summary of weekly reports from cities, January 15 to February 18, 1928—Annual rates per 100,000 population compared with rates for the corresponding period of 1927 [1]

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended February 4, 1928.—The following report for the week ended February 4, 1928, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations located at Singapore to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt.—Suez.
Aden Protectorate.—Aden.
India.—Bombay, Rangoon
Ceylon.—Colombo.
Dutch East Indies. Makassar.

CHOLERA

India.—Bassein, Calcutta, Rangoon
Siam. Bangkok.

SMALLPOX

Ceylon.—Colombo.
India.—Bombay, Calcutta, Madras, Moulmein, Negapatam, Rangoon, Tuticorin, Vizagapatam.
French India.—Pondicherry.
Dutch East Indies.—Banjermasin, Belawan-Deli Pontianak.
Straits Settlements. Singapore.
China.—Hong Kong, Shanghai.
Kwantung.—Dairen
Manchuria.—Mukden

Returns for the week ended February 4 were not received from Balikpapan, Dutch East Indies, Canton, China, or Vladivostok, Union of Socialist Soviet Republics.

ANGOLA

Epidemic cerebrospinal meningitis in the plateau region—Suspect plague at Benguela.—Under date of January 11, 1928, epidemic cerebrospinal meningitis was reported present in the high plateau region of Angola. Under the same date two suspect cases of plague were reported at Benguela.

ARABIA

Aden—Plague—Increased prevalence—January 31, 1928.—Information received from Aden, Arabia, under date of January 31, 1928, shows increased prevalence of plague at that port, with 77 cases and 33 deaths reported to that date. The history of the outbreak indicates that plague was discovered January 9, and that 27 cases with 13 deaths were reported from that date to January 11, 1928. The disease was stated at that date to be confined to a section of the town inhabited by coal coolies. This population group was removed and isolated in quarantine. On January 24, spread of infection outside the original focus and contacts was noted and plague was stated to be present in epidemic form.

BELGIAN CONGO

Boma—Matadi—Yellow fever—December 24, 1927, to January 19, 1928.—Information from the Government of Belgium, dated February 4, 1928, shows 1 fatal case of yellow fever at Boma, Belgian Congo, in a sailor from the steamship *Manpoko*, and 31 cases with 18 deaths at Matadi, Belgian Congo, from December 24, 1927, to January 19, 1928. Of the cases at Matadi, 16 with 8 deaths were in Europeans.

CANADA

Provinces—Communicable diseases—Week ended February 18, 1928.—The Canadian Department of Health reports cases of certain communicable diseases from six Provinces of Canada for the week ended February 18, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Total
Influenza	18			4			22
Lethargic encephalitis					1		1
Smallpox				40		7	47
Typhoid fever			29	5		1	35

Quebec Province—Communicable diseases—Week ended February 18, 1928.—The Bureau of Health reports cases of certain communicable diseases for the week ended February 18, 1928, as follows:

Disease	Cases	Disease	Cases
Chicken pox	40	Scarlet fever	128
Diphtheria	48	Smallpox	11
German measles	3	Tuberculosis	44
Influenza	7	Typhoid fever	31
Measles	251	Whooping cough	14

Quebec Province—Vital statistics—December, 1927.—Births and deaths in the Province of Quebec for the month of December, 1927, were reported as follows:

Estimated population	2,604,000	Deaths from—Continued	
Births	6,071	Heart disease	839
Birth rate per 1,000 population	28.0	Influenza	68
Deaths	2,724	Measles	16
Death rate per 1,000 population	12.6	Pneumonia	245
Deaths under 1 year	698	Poliomyelitis	1
Infant mortality rate	115	Scarlet fever	16
Deaths from—		Smallpox	2
Accidents	61	Syphilis	2
Cancer	118	Tuberculosis (pulmonary)	168
Cerebrospinal meningitis	5	Tuberculosis (other forms)	35
Diabetes	19	Typhoid fever	16
Diarrhea	123	Whooping cough	37
Diphtheria	51		

ECUADOR

Guayaquil—Plague—Infected rats—January, 1928.—During the month of January, 1928, four cases of plague with four deaths were reported at Guayaquil, Ecuador. During the same period, 23,812 rats were reported examined at Guayaquil and 23 rats found plague infected.

Smallpox.—During the two weeks ended January 15, 1928, two cases of smallpox were reported at Guayaquil.

EGYPT

Plague—Province of Assiout—Suez—January 31–February 1, 1928.—Plague has been reported in Egypt as follows: Assiout Province, one fatal case, bubonic; Suez, two fatal cases, one bubonic, one septicemic.

ESTONIA

Communicable diseases—December, 1927.—During the month of December, 1927, communicable diseases were reported in the Republic of Estonia as follows:

Disease	Cases	Disease	Cases
Diphtheria	50	Tuberculosis	108
Measles	46	Typhoid fever	28
Scarlet fever	493		

Population, officially estimated, 1,114,630.

MADAGASCAR

Plague—December 1–15, 1927.—During the period December 1 to 15, 1928, 145 cases of plague with 134 deaths were reported in the Island of Madagascar. The occurrence was distributed according to Provinces as follows: Antisirabe, cases and deaths, 34; Itasy, cases 25, deaths, 24; Moramanga, cases 17, deaths 14; Tananarive, exclusive of the town of Tananarive, cases 55, deaths 49; Tananarive Town, cases 14, deaths 13. The distribution according to type was: Bubonic, cases 91; pneumonic, 19; septicemic, 35. Mortality according to type was: Bubonic, 80 deaths; pneumonic, 19; septicemic, 35.

MEXICO

Epidemic smallpox—Typhoid fever—State of Jalisco, Mexico—February, 1928.—According to press reports dated February 11, 1928, smallpox in epidemic form was reported present in the Los Altos region of the State of Jalisco, Mexico, the principal urban locality affected being the town of Atotonilco el Alto. Some prevalence of typhoid fever was also reported. The epidemic outbreak was explained as being induced by concentration of population in the region affected, due to local disturbances in the Los Altos district.

POLAND

Communicable diseases—1927.—The following table gives a summary of the number of the principal communicable diseases reported in Poland for the year 1927, with the deaths from these diseases and the case and death rates per 100,000 population.

Disease	Cases	Deaths	Rates per 100,000	
			Cases	Deaths
Diptheria	9,685	838	32.2	2.7
Measles	41,888	901	139.6	3
Scarlet fever	36,379	3,224	121.1	10.7
Trachoma	13,029		43.7	
Typhoid fever	19,129	1,477	63.7	4.9
Typhus fever	2,934	266	9.7	.8
Whooping cough	9,478	719	31.5	2 3

VIRGIN ISLANDS

Communicable diseases—January, 1928.—During the month of January, 1928, communicable diseases were reported in the Virgin Islands of the United States as follows:

Island and disease	Cases	Remarks
St. Thomas and St. John:		
Chancroid	1	
Dengue	4	
Erysipelas	1	St. John.
Gonorrhea	3	
Malaria	2	Benign tert n.
Syphilis	1	Secondary.
Tetanus	2	
Tuberculosis	1	Chronic pulmonary.
Whooping cough	2	
St. Croix:		
Diphtheria	1	
Gonorrhea	1	
Syphilis	9	Secondary
Uncinariasis	4	Necator americanus

YUGOSLAVIA

Communicable diseases—January, 1928.—During the month of January, 1928, communicable diseases were reported in Yugoslavia as follows:

Disease	Cases	Deaths	Disease	Cases	Deaths
Anthrax	17	4	Poliomyelitis		1
Cerebrospinal meningitis	11	7	Rabies	1	1
Diphtheria	235	59	Scarlet fever	1,548	216
Dysentery	23	1	Tetanus	10	2
Leprosy	1		Typhoid fever	262	33
Measles	2,141	28	Typhus fever	7	3

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

TREASURY DEPARTMENT

PUBLIC HEALTH REPORTS

ISSUED WEEKLY

BY THE UNITED STATES PUBLIC HEALTH SERVICE

VOLUME 43 :: :: NUMBER 11

MARCH 16 - - - 1928

SPECIAL ARTICLES

UNITED STATES
GOVERNMENT PRINTING OFFICE
WASHINGTON
1928

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

Asst. Surg. Gen. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

ADDITIONAL COPIES
OF THIS PUBLICATION MAY BE PROCURED FROM
THE SUPERINTENDENT OF DOCUMENTS

PREVALENCE OF DISEASE

PUBLIC HEALTH REPORTS

VOL. 43 MARCH 16, 1928 NO. 11

IMPORTANCE OF RESPIRATORY DISEASES AS A CAUSE OF DISABILITY AMONG INDUSTRIAL WORKERS[1]

By DEAN K. BRUNDAGE, *Assistant Statistician, United States Public Health Service*

A 10-year record of disabling illnesses among employees of the Edison Electric Illuminating Co. of Boston showed that 54 per cent of the absences on account of sickness among the men was caused by the respiratory[2] group of diseases. This record is of especial interest because it includes all disabilities lasting one working day or longer during the decade ending December 31, 1924.[3]

From the reports of a group of industrial sick-benefit associations, of cases of illness causing disability for eight consecutive days or longer among the male members of the associations, it was found that respiratory diseases caused 47 per cent of the illnesses. In these reports, which covered the period from 1921 to 1926, inclusive, the number of men included averaged nearly 100,000 annually, or a total of approximately 570,000 years of life under observation during the six-year period.[4]

Thus, whether we consider all cases of disabling sickness or only those which caused disability for a period longer than one week, we find that respiratory diseases constituted approximately one-half of the cases. From the standpoint of effect upon the absence rate in industry, no other disease group approached in importance the respiratory diseases. Among employees of the Edison Co. diseases of the respiratory system caused more absences from work than all other diseases put together.

TIME LOSSES CAUSED BY THE RESPIRATORY DISEASES

The sickness records of the Edison Co. revealed an annual loss of 3.23 calendar days of disability[5] from respiratory diseases per male employee, compared with 6.92 calendar days of disability from all

[1] From the Office of Industrial Hygiene and Sanitation in cooperation with the Office of Statistical Investigations of the United States Public Health Service.

[2] Including influenza and grippe, tuberculosis of the lungs, diseases of the pharynx and tonsils, colds and other diseases of the nasal fossae, etc., i. e. title numbers 11, 31, 109, and 97-107 in the International List of the Causes of Death, third revision, Paris, 1920.

[3] For details of this study, see "A Ten-Year Record of Absences from Work on Account of Sickness and Accidents." Pub. Health Rep., vol. 42, No. 8 (Feb. 25, 1927), pp. 529-550. (Reprint No. 1142)

[4] For more detailed information in regard to the reporting sick-benefit associations, see "Sickness Among Industrial Employees." Pub. Health Rep., Vol 41, No. 4 (Jan. 22, 1926), pp. 113-131. (Reprint No. 1060.)

[5] Number of calendar days intervening from the date disability began to the date of return to work.

causes of sickness per man on the pay roll. Diseases of the respiratory system, accordingly, accounted for 47 per cent of the time lost; and, as has been mentioned, for 54 per cent of the number of absences due to illness.

The records of the reporting sick-benefit associations show a smaller proportion of time lost from the respiratory diseases. In the associations having a benefit period of 13 weeks, this disease group caused 34 per cent of total calendar days of disability from all diseases; in the associations with a benefit period of 26 weeks the percentage was 35; and in those associations in which the maximum period of benefit payments is 52 weeks, respiratory diseases caused 32 per cent of the total number of days of disability. In the sick-benefit associations, however, no record is kept of the time lost after the close of the benefit period for those members who are still disabled after they have drawn maximum benefits, and hence these time-lost percentages are not as accurate as those based on the number of days lost among employees of the Edison Co.

TABLE 1.—*Respiratory diseases causing absence from work for one day or longer among employees of the Edison Electric Illuminating Co. of Boston in the 10 years ending December 31, 1924*

Respiratory diseases causing disability (with corresponding title numbers in parentheses from the International List of the Causes of Death, Third Revision, Paris, 1920)	Number of absences	Number of days of disability [1]	Annual number of absences per 1,000 on the pay roll	Calendar days per absence [1]	Annual number of days of disability per person on the pay roll

Other diseases of the respiratory system (103-107)	15	542	4	36.13	.145

[1] Number of calendar days from the date disability began to the date of return to work.

TABLE 2.—*Respiratory diseases causing disability for eight consecutive days or longer among a group of men employed in several different industries. Average annual frequency, 1921–1926, inclusive*

(Number of years of life under observation 570,012)

Respiratory diseases (with corresponding title numbers in parentheses from the International List of the Causes of Death, third revision, Paris, 1920)	Annual number of cases per 1,000 men	Number of cases
Sickness, exclusive of accidents [1]	90.9	51,823
Respiratory diseases (11, 31, 97–107, 109)	43.1	24,549
Bronchitis—acute and chronic (99)	5.7	3,238
Diseases of the pharynx and tonsils (109)	6.4	3,619
Influenza and grippe (11)	20.8	11,869
Tuberculosis of the respiratory system (31)	1.5	837
Pneumonia, all forms (100, 101)	3.3	1,884
Other diseases of the respiratory system (103–107)	5.4	3,102

[1] An understatement of the number of cases causing disability for more than one week, because most of the reporting industrial mutual associations do not pay sick benefits for the venereal diseases, for illness resulting from the violation of any civil law, for the results of willful or gross negligence, and for certain other causes. Some associations do not pay for chronic diseases contracted prior to the date of joining the organization, nor for disabilities caused by or growing out of specific physical defects.

RELATIVE FREQUENCY OF THE DIFFERENT RESPIRATORY DISEASES CAUSING DISABILITY

The record of disabilities of one day or longer during the 10 years from 1915 to 1924, inclusive, showed that the common cold was by far the worst offender in the family of respiratory diseases as a cause of disability among a group of male employees. Diseases of the nasal fossae (mostly colds) occurred at nearly six times the rate of diseases of the pharynx and tonsils, which was the next most frequent respiratory disease group. Influenza and grippe occupied third place, and bronchitis fourth. The rates as shown in Table 1 were as follows:

Relative frequency of different respiratory diseases causing disability for one day or longer—Experience of male employees of the Edison Electric Illuminating Co. of Boston, 1915–1924, inclusive

Respiratory diseases	Annual number of absences per 1,000 men	Per cent of total respiratory cases
All respiratory diseases	564	100
1. Colds and other diseases of nasal fossæ	400	71
2. Diseases of the pharynx and tonsils	69	12
3. Influenza and grippe	51	9
4. Bronchitis	18	3
All other respiratory diseases	26	5

The respiratory picture is rather different when one leaves out of account the disabilities lasting one week or less, as is done in the data of the sick-benefit organizations. The common cold, which caused 71 per cent of the absences from diseases of the respiratory system, disabling 4 out of 10 men for 3.4 days annually and 7 out of 10 women for 3.1 days each year, drops out of the picture when only the eight-day and longer illnesses are considered. Diseases of the pharynx and tonsils, however, again occupied second place. The incidence rate of bronchitis was third from the highest, and of pneumonia (all forms) fourth, in this array. The rates as shown in

Table 2 were as given below. The large number of respiratory cases which cause disability for less than eight days is indicated from a comparison of the rates shown in the table above with those given in the following table:

Relative frequency of different respiratory diseases causing disability for eight consecutive days or longer—Experience of male members of sick-benefit associations which reported their cases to the United States Public Health Service, 1921–1926, inclusive

Respiratory diseases	Annual number of cases per 1,000 men	Per cent of total respiratory cases
All respiratory diseases	43.1	100
1. Influenza and grippe	20.8	48
2. Diseases of the pharynx and tonsils	6.4	15
3. Bronchitis	5.7	13
4. Pneumonia (all forms)	3.3	8
All other respiratory diseases	6.9	16

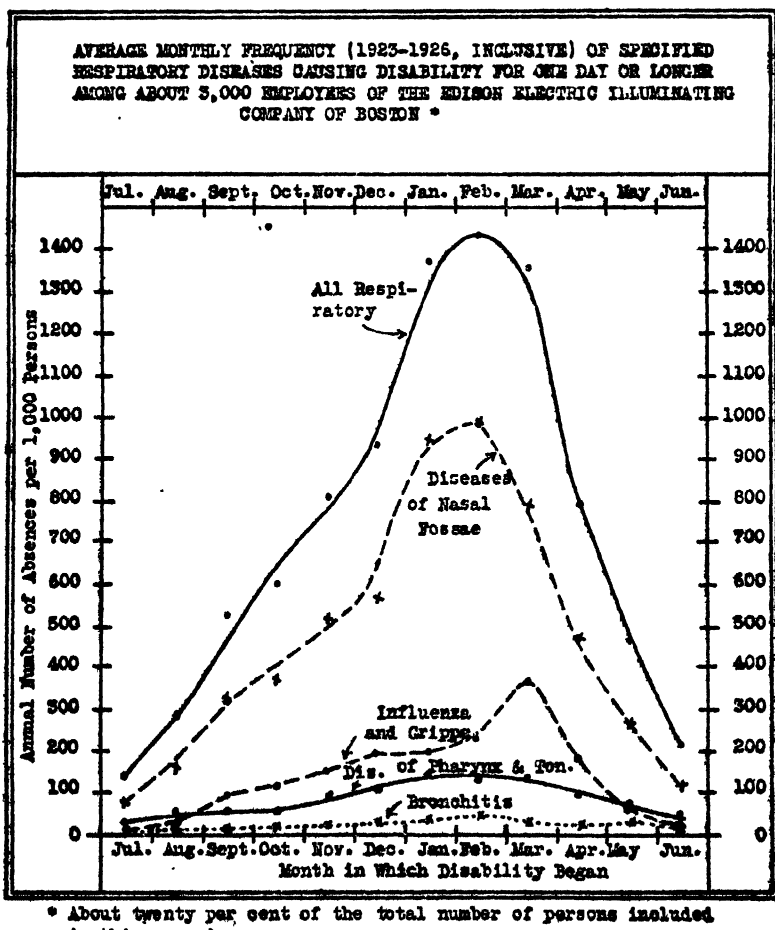

FIG. 1

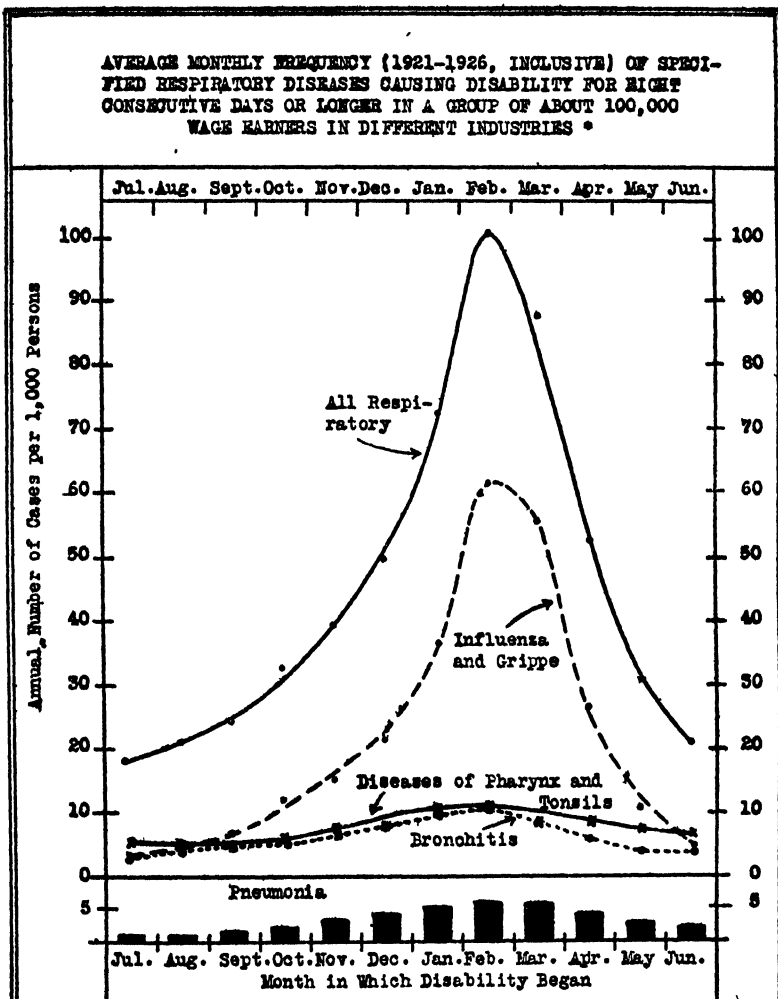
SEASONAL NATURE OF RESPIRATORY DISEASES

The tendency for respiratory disease incidence to vary in accordance with the season of the year is measured in Tables 3 and 4, and the rates are plotted in Figures 1 and 2. The records for disabilities of one



* About ten per cent of the total number of persons included in the record were women.

FIG 2

day or longer and of eight days or longer both showed the minimum respiratory incidence rate in the month of July and the maximum rate in February.

An interesting difference was revealed in the curve for all respiratory diseases in the two sets of data. Respiratory disabilities lasting

longer than one week occurred oftener in March than in January, and more frequently in April than in December. In contrast, the record for disabilities of one day or longer indicated practically the same respiratory rate in March as in January, and a lower rate in April than in December. Attacks of respiratory sickness having their onset in the late winter and early spring evidently tend to be more prolonged than those which begin in the early part of winter. From this it appears that industrial workers possess less resistance to respiratory infections toward the end of winter than at its beginning.

TABLE 3.—*Average monthly frequency (1923–1926, inclusive) of specified respiratory diseases causing disability for one day or longer among employees (approximately 3,000) of the Edison Electric Illuminating Co. of Boston* [1]

Month in which disability began	Annual number of absences per 1,000 persons

[1] About 10 per cent of the total number of persons included in this table were women.
[2] Nonindustrial accidents included.
[3] Disease numbers 31, 97, 98, 102–107 in the International List of the Causes of Death, third revision, Paris, 1920.

The tremendous upswing from September to February, and the even more abrupt decline from February to May, in the frequency of diseases of the respiratory system causing absence from work for one day or longer, results largely from the seasonal characteristic of the common cold. There were twelve times as many disabilities from colds and other diseases of the nasal fossæ in midwinter as in midsummer. (See Table 3.)

The seasonal extremes in sickness incidence were not so wide when the more serious respiratory cases only were considered, i. e., those which kept employees away from work for more than one week. The curve for such cases, however, was decidedly steep, largely on account of the marked seasonal tendency in the incidence of the eight-day or longer cases of influenza and grippe. Diseases of the pharynx and tonsils, and bronchitis exhibited no such abrupt rise and decline according to season as was shown for influenza and grippe, and, to a lesser extent, for the pneumonias. (See Table 4 and fig. 2.)

VARIATION IN THE FREQUENCY OF RESPIRATORY DISEASES IN DIFFERENT COMPANIES

The frequency of disability lasting eight days or longer on account of diseases of the respiratory system varied greatly among the 26 industrial sick-benefit associations which reported their claims to the United States Public Health Service throughout the three years ending December 31, 1926. In the establishment showing the lowest respiratory rate for these three years, the incidence was only 17 cases a year per 1,000 men; in the establishment having the highest respiratory rate there were 85 cases a year per 1,000 men. There were thus just five times as many cases of respiratory disease causing disability for a period longer than one week per 1,000 men on the pay roll in the establishment having the most respiratory sickness as in the plant showing the lowest respiratory frequency rate.

TABLE 5.—*Frequency of respiratory diseases causing disability for eight consecutive days or longer among males during the three years ending December 31, 1926, by establishments which reported to the United States Public Health Service throughout this period*

Wide differences in death rates as well as in rates of sickness from the respiratory diseases as a whole and from specific diseases of the respiratory system are found in different States, cities, and communities. To cite only one example, the death rate from pneumonia (all forms) in Akron, Ohio, during the 11 years ending December 31, 1920, was 138 per 100,000 population; in Youngstown, which is only 53 miles from Akron, the pneumonia death rate was 268 per 100,000; and in East Youngstown the rate was 484 per 100,000 population during these 11 years

It is evident that the causes of wide differences in the incidence of respiratory diseases and in the severity of such illnesses as measured by the death rate should be investigated and thoroughly understood before any considerable measure of success is to be expected in the prevention or control of these diseases among large groups of the industrial population. In view of the frequency of disability and the amount of time lost from work on account of the respiratory diseases, even a small degree of success in their prevention would contribute enormously to the sum total of physical and mental energy, to the number of days that the industrial population is physically able to work, and, accordingly, to an enhanced national prosperity. It appears that there is not only a field, but an urgent need, for study of the factors which cause such wide variations in the frequency of respiratory diseases among different groups of industrial workers. One such study is being made of a specific respiratory disease. The United States Public Health Service is attempting to measure and evaluate the more important factors affecting the incidence and severity of lobar pneumonia. Records are being kept of the pneumonia cases and the conditions under which they occur in certain groups of industrial employees known to have a high rate, and in other groups experiencing average or less than average pneumonia frequency. Analysis of the records, it is believed, will cast light upon the influence of some of the more important causes of high sickness and death rates from the disease, and contribute something to that knowledge which, obviously, is prerequisite to real control and prevention of the respiratory diseases.

RAT-FLEA SURVEY OF THE PORT OF SAN JUAN, PORTO RICO—A PRELIMINARY REPORT

By O. H. Cox, *Surgeon, United States Public Health Service, Chief Quarantine Officer for Porto Rico;* Arturo L. Carrion, M. D., *Chief Bureau of Plague Prevention, Department of Health of Porto Rico;* and Carroll Fox, *Surgeon, United States Public Health Service*

A rat-flea survey was in progress in the port of San Juan, Porto Rico, during the fiscal year 1927, as a part of a general program of the United States Public Health Service to make rat-flea surveys in the principal seaports of the United States as an aid in estimating their plague infectibility. The survey is still under way and will be continued until sufficient data are secured to substantiate definite conclusions. This paper briefly records the results of the first year's work. Although the total numbers are not very large, the trend appears to be sufficiently definite to warrant publication at this time, and will be followed in time by a full report of the completed survey.

The survey in San Juan is a cooperative effort between the United States Public Health Service Office of Maritime Quarantine for the Island of Porto Rico and the Bureau of Plague Prevention of the Insular Health Department.

METHODS

Specific procedures prescribed for flea surveys in seaports and as used at the New York quarantine station have been closely followed. These are, in general, the methods adopted by Fox and Sullivan of the Public Health Service in their rat-flea surveys in several American seaports (see Public Health Reports, September 11, 1925), and are based upon the experience of Public Health Service officers in plague-eradicative campaigns at San Francisco, New Orleans, and other cities.

Rats, trapped alive in cage traps, were brought to the laboratory without removing them from the traps and without covering the traps. At the laboratory the rats were killed by a blow on the head and each was then suspended over night, separately, in deep glass jars containing some water. In the morning the rats' fur was thoroughly ruffled, or combed within the jar, to dislodge any remaining fleas, and all the fleas from each rat were then collected from the surface of the water and kept in separate groups. Each group of fleas was cleared in potassium hydroxide, passed through water and alcohol to xylol, and finally mounted in balsam on a slide, scattered under a cover glass. Each slide was definitely marked to identify it with its rat host and the location where caught, and the fleas were then identified under the microscope. Sample specimens and doubtful fleas were sent to Surg. Carroll Fox at the New York quaran-

tine station for confirmatory determination. Careful record was kept of the locations where the rats were caught, the numbers of traps set, the species and sex of the rats caught, and the fleas recovered from each rat. Records were also maintained of the variations obtaining in temperature and humidity during the period of the survey.

The city was divided into four zones. Zone I included all docks; Zone II, the water front, including all structures adjacent to the docks; Zone III, the commercial district not on the water front; and Zone IV all other portions of the city. The area of San Juan is extensive in comparison with the population and includes some rather sparsely settled areas, particularly in Zone IV.

It should be stated that the insular government has for several years been trapping rats (in snap traps) for the purpose of lowering the rat population of the city. This has probably tended to decrease the number of live rats caught and to modify their apparent distribution.

While the results reported cover the fiscal year 1927, beginning July 1, 1926, the actual trapping of live rats began July 12, 1926. The numbers for the first month, therefore, are small.

RESULTS

During the fiscal year ended June 30, 1927, there were trapped 360 live rats, from 193 of which were secured 2,575 fleas. Of these fleas, 2,539 were *Xenopsylla cheopis*, 35 were *Echidnophaga gallinacea*, and 1 was *Ctenocephalus canis*. On the basis of these figures we have a total flea index of 7.15 (fleas per rat) and an *X. cheopis* index of 7.05.

For plague-preventive purposes it is almost as important to know where the fleas are as to know how many and what kinds there are. In Table 1 the total flea index of the different zones is given. Since 95 per cent of the fleas are *X. cheopis*, this table very nearly represents the *X. cheopis* index.

TABLE 1.—*Flea index in the various zones*

	Zone I	Zone II	Zone III	Zone IV
Percentage of rats with fleas	85.7	36.3	70 0	25.2
Number of fleas per rat (average)	14.4	2.8	6.2	1.8

It will be at once noted that in Zone I, which includes the docks, the index is much higher than in any other zone, both in percentage of rats with fleas and in numbers of fleas per rat. In this zone was secured the rat with the largest number (124) of fleas, a female Norway, captured at the insular dock. The next highest figures are in Zone III, the commercial district.

The flea index for the different months of the year is set forth in Table 2.

TABLE 2.—*Flea indices for the various months*

	July	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	May	June
Percentage of rats with fleas	100	60	65	72	93	51	62	52	30	40	48	55
Number of fleas per rat (average)	7	4	8.1	6.3	9	6.2	7.8	5	4.3	5.3	14.4	11

For the year:
Percentage of rats with fleas 54.0
Fleas per rat (average) 7.2

On Chart 1 is plotted the number of fleas per rat and the temperature and humidity curves.

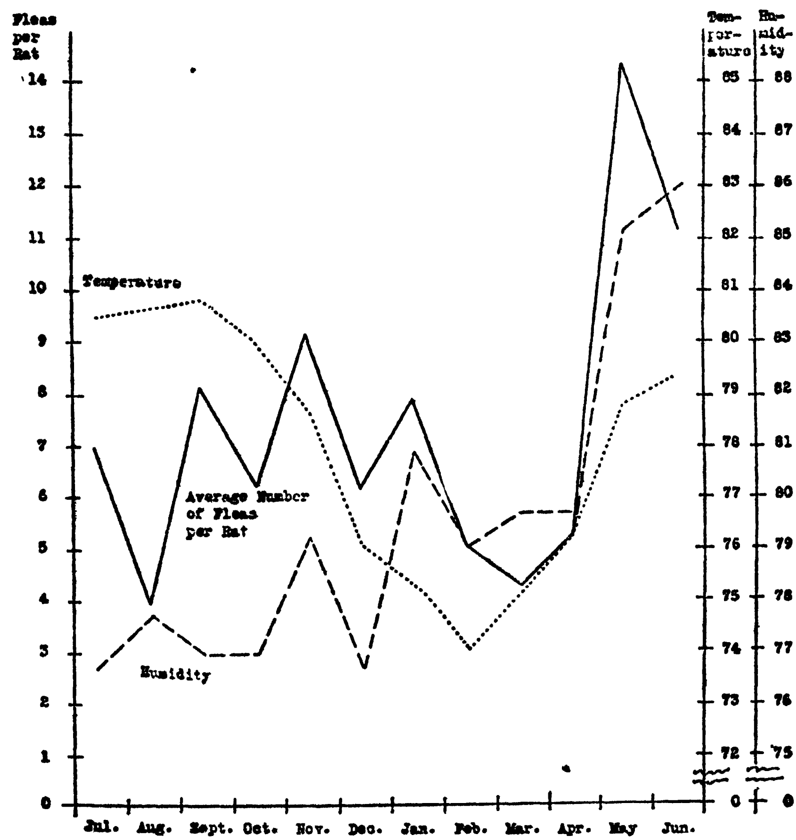

CHART 1.—Graphs showing the average number of fleas found per rat, the temperature, and the humidity in the port of San Juan, Porto Rico, July, 1926–June, 1927

As will be seen, there is no great variation except in May and June. In apportioning the relatively few rats among the different months the numbers become too small to have much meaning. However, the concurrence of a sharp rise in fleas per rat with a similar sharp

rise in humidity and a rise in temperature is probably significant. It agrees with similar observations in many other parts of the world. A study of the temperature and humidity curves reveals, however, that climatic conditions are favorable for the breeding of *X. cheopis* throughout the entire year.

The flea indices for the different species of rat are given in Table 3.

TABLE 3.—*Flea indices for different species of rats*

	Rattus norwegicus [1]	Rattus rattus	Rattus alexandrinus	Totals
Number of rats	287	41	32	360
Number of fleas	2,094	352	129	2,575
Percentage of rats with fleas	48	83	66	53.61
Fleas per rat (average)	7.3	8.6	4	7.15

[1] This rat, the common rat of seaports in the Western Hemisphere, has been given many names, such as the "brown rat," the "Norway rat," "*Mus decumanus*," "*Epimys decumanus*," etc.

It is to be remarked that the total flea index found for the black rat (*Rattus rattus*) is higher than that for the Norway rat. This is not in agreement with observations made in other tropical countries where the total flea index for the Norway rat is usually twice that for the black rat. The *Rattus alexandrinus* is generally regarded as a variety of the *Rattus rattus* and harbors, as a rule, about the same number of fleas. The total number of rats is rather small, which may possibly account for these results.

DISTRIBUTION OF RATS

From Zone I were secured 39 per cent of all the rats. This was due largely to more intensive trapping in this area. Zones IV, II, and III followed, respectively, with 34 per cent, 21 per cent, and 6 per cent.

Records of the numbers of traps set are available only between the dates July 12, 1926, and February 8, 1927. From these records has been compiled Table 4.

TABLE 4.—*Number of rats per 1,000 traps in the various zones*

	Zone I	Zone II	Zone III	Zone IV
Total number of traps set	9,546	1,118	2,286	5,606
Number of rats caught	75	30	13	54
Number of rats per 1,000 traps set	7.9	26.8	5.7	9.6

Zone II is apparently by far the most heavily rat infested, which is surprising in view of the low flea index in this zone.

The Norway rat was found to be markedly predominant. This was to be expected, for two reasons: First, this is the predominant rat

in seaports in the Western Hemisphere; and, second, it is much more easily caught in cage traps than is the black rat or the alexandrian rat, which is notoriously shy of this type of trap. In Chart 2 is shown graphically the apparent concentration of the different varieties in the various zones.

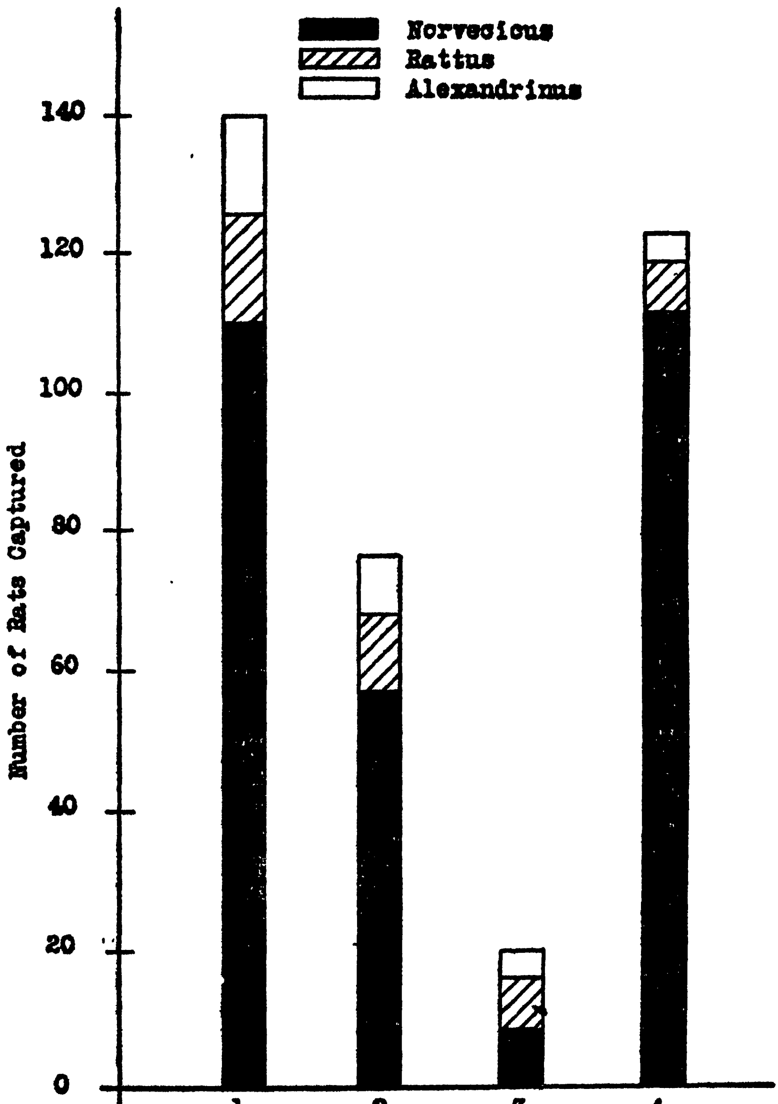

CHART 2.—Graphic representation of relative numbers of rats of different species captured in the different zones in the port of San Juan, Porto Rico, July, 1926–June, 1927

CONCLUSIONS

(1) A rat-flea survey of San Juan, P. R., carried on during the fiscal year 1927, resulted in the capture of 360 live rats, from which were secured 2,575 fleas, 95 per cent of which were *Xenopsylla cheopis*.

(2) On these figures a total rat-flea index of 7.15 is indicated, and an *X. cheopis* index of 7.05.

(3) The total flea index on the docks is much higher than elsewhere in the city, the commercial district being next, then the water front, and last all other portions of the city. The respective figures are 14.4, 6.2, 2.8, and 1.8.

(4) Temperature and humidity conditions are favorable for flea breeding throughout the year. There was a marked rise of the index in May and June, coincident with a similar rise in humidity and a rise of temperature.

(5) *Rattus norvegicus* is the predominant rat.

COURT DECISIONS RELATING TO PUBLIC HEALTH

Phosphorus poisoning held not compensable under workmen's compensation act.—(Virginia Supreme Court of Appeals; Turner *v.* Virginia Fireworks Co. et al., 141 S. E. 142; decided January 19, 1928.) An employee of a fireworks company sought compensation for phosphorus poisoning contracted in the course of her employment. The State industrial commission found that it was her duty to handle white phosphorus, and that, in rubbing an aching tooth with her fingers, she conveyed the poison to her mouth. The workmen's compensation statute provided:

"Injury" and "personal injury" shall mean only injury by accident arising out of and in the course of the employment and shall not include a disease in any form, except where it results naturally and unavoidably from the accident.

Compensation was denied by the commission on the ground that the claimant had not sustained an accident within the meaning of the compensation law. On appeal the supreme court of appeals upheld the action of the commission, stating as follows in the opinion:

* * * Whether or not the rubbing of the aching tooth with her fingers and getting poison in her mouth was an accident, within the meaning of the workmen's compensation act, we deem it unnecessary to decide. If it be admitted that it was an accident, it does not follow that the phosphorus poison from which she suffered was the natural and unavoidable result of the accident. The diseased tooth was exposed to phosphorus fumes before she rubbed it, and it is equally probable that the poison resulted from the phosphorus fumes to which it was exposed rather than the rubbing of the tooth * * *.

If claimant's injuries were the natural and unavoidable result of an accident, she should be allowed compensation, but if they resulted from an occupational

disease, without an accident, there can be no recovery. Since the disease may have resulted from either of the two causes, for one of which the employer is liable and for the other of which he is not liable, the burden was on the claimant to show that the injuries resulted from the former.

* * * * * * *

There being no proof that the injury to the claimant resulted naturally and unavoidably from the rubbing of the phosphorus upon her tooth, the judgment of the commission will be affirmed.

Convictions for taking clams from proscribed area upheld.—(Massachusetts Supreme Judicial Court; Commonwealth *v.* St. John, and six other cases, 159 N. E. 599; decided January 5, 1928.) Several persons were found guilty of taking clams illegally from certain tidal waters and flats which had been examined by the State department of public health, acting under a State law, and determined to be contaminated, and also were found guilty of possessing clams so taken. One of the defendants was also convicted of transporting clams so taken. On appeal, the supreme court overruled the exceptions of the defendants and sustained the convictions.

Attempt of venereally-infected husband to force wife to have sexual intercourse held extreme cruelty.—(New Jersey Court of Chancery; Lazarwitz *v.* Lazarwitz, 139 A. 881; decided January 13, 1928.) In a divorce proceeding it was held that the attempt of a husband, who, to his own knowledge, was suffering from syphilis, the Wassermann test resulting in a four plus report, to force his wife to have sexual intercourse with him against her will constituted extreme cruelty under the terms of an act authorizing divorce from the bonds of matrimony for extreme cruelty.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Sewerage Systems, with Special Reference to Run-Off of Surface Waters. M. H. Limb. *The Surveyor*, vol. 72, No. 1872, December 9, 1927, pp. 567–570. (Abstract by H. W. Streeter.)

A concise résumé of present-day practice in the design of sewerage systems, as based on British experience. A general description is given of the types of sewerage systems, materials of construction, and methods of determining the flow of domestic sewage, trades wastes, and storm water. The remainder of the paper is devoted to describing, with illustrative examples, methods of determining maximum storm-water flows and times of concentration at specified points. The description is illustrated by charts and sketches showing typical layouts; a particularly useful diagram being one (fig. 4) showing the relation between rainfall intensity and time of concentration. The various formulæ for this relation are discussed and practical methods, both analytical and graphical, for applying these formulæ to the design of storm-water sewers are described. The author notes that so many variable factors are involved in each problem that it is impossible to reduce the subject to the mathematical precision possible with other engineering subjects.

Digestion of Sewage Screenings. H. Heukelekian. *Public Works*, vol, 58, No. 12, December, 1927, pp. 455–457. (Abstract by A. S. Bedell.)

The digestion of screenings from a fine screen, seeded with ripe sludge, was tried out with and without fresh solids. "Fresh solids" is material collected by sinking pails in flow chamber of an Imhoff tank, thus securing settled solids of the screened sewage. Lime was added to a duplicate series to adjust and maintain the reaction to a pH value of 7.4. To a 2:1 mixture of fresh solids and ripe sludge 11.2 per cent screenings were added on the basis of volatile matter. The mixture of screenings and ripe sludge had a ratio of 1:1 on the basis of volatile matter. Frequent gas measurements and occasional gas analyses were made. Solids and ash were determined in the beginning and at the end.

The results indicate that the digestion of screenings, either separately or in conjunction with fresh solids, is feasible. The rate of digestion of screenings was as rapid as that of the screened fresh solids. The volume of gas produced from screenings was as high as that from fresh solids. About equal amounts of lime were necessary for the digestion of screenings and of fresh solids. In general, the effects of liming were practically negligible.

Paper Wastes: Investigation of the Recirculation and Treatment of Waste Waters from the Process of Paper Making. I. R. Riker. *Public Health News*, New Jersey State Department of Health, vol. 12, No. 10–11, September–October, 1927, pp. 290–303. (Abstract by G. H. Hazlehurst.)

Pollution of streams in New Jersey by paper-mill wastes has been a serious problem for the past decade. No type treatment in the State has been entirely successful. Mill owners objected to the recirculation and reuse of water (closed system), because water soured and slime was produced, hindering the process of paper making.

The mill investigated and reported on had four paper-making machines. All waste white water was being reused. Two recirculating systems were operated. One used chemical precipitation of wastes, and this water was used for felt showers with make-up waste rates of 3 to 1. The other system returned waste white water direct from pits to breakers or beaters. Chemical precipitation plant handles all water over and above that used by breakers or beaters. "Boothall," a balanced coagulant, is used. Reclaimed stock from precipitation plant makes up 20 per cent of the material used by No. 1 machine; that is, 15 tons of finished material is procured from 12 tons of old newspaper stock (raw material).

After the investigation was made it was reported that all waste white water was being used and that for long periods it was unnecessary to pollute the creek with this waste.

The Development of Tanks for the Bacterial Treatment of Sewage. A. C. Hewitt. *The Commonwealth Engineer*, vol. 15, No. 4, November 1, 1927, pp. 157–158. (Abstract by E. C. Sullivan.)

This article outlines the development of the Cameron tank in 1895, the Travis tank in 1903, and the Imhoff tank in 1907. The particular advantages or claims made for these various types of tanks are given, as well as the principles involved in their designs.

The development of the activated sludge process is also traced. Mention is made of research conducted during the past four years to obtain information about various points as follows: (*a*) Deciding what preliminary treatment, if any, should be given to the sewage before aeration; (*b*) endeavoring to reduce operation costs by perfecting the method of aeration; (*c*) ascertaining the best method of treating the large amount of sludge which results from activation.

Details of studies on these particular points are given, including the addition of an activated sludge plant to the existing Imhoff tank plant at Essen, Germany, and the digestion of excess sludge in the Imhoff tanks; the use of mechanical

agitators at Sheffield, England, to obtain oxygen from the air; and of the measures taken for the conditioning of sludge at Chicago, Ill., Milwaukee, Wis., and Houston, Tex.

Annual Report, Department of Health, Government of Palestine, 1926. 92 pages. (Abstract by I. W. Mendelsohn.)

Typhoid fever.—Epidemics occurred in Emek Jezriel, Tel Aviv, and Jerusalem, with 206, 223, and 280 cases, respectively. The total incidence for the country was 1,402, as compared with 705 in 1925.

There was no evidence to incriminate water as the definite cause, nor could the outbreaks be attributed to milk or other foods, though in some towns the sale of vegetables fertilized with sewage constituted a constant possible means of spreading infection. Infection from carriers and by contact from cases was regarded as an important factor assisted by late notification, delayed hospitalization of cases, and overcrowding in insanitary quarters of towns and in new settlements.

Malaria control.—The decrease in malaria incidence in the country has continued. At the end of the year, 21,000 of the 60,000 possible breeding places on record in towns had been permanently mosquito-proofed, while over 12,000 (or a total of 23,000) such places in the villages had been dealt with. Seven thousand and thirty nine pumps had been fitted to cisterns. Oil and Paris green were used in control measures.

The 12 demonstration areas controlled by the malaria research unit were the same as in 1925, the methods of control consisting of hand collection or "smoking" out of mosquitoes in January and February, before the breeding season started; examination of potential larval breeding places at the end of March after the heavy rains; and institution of antilarval measures (Paris green or oil) and minor drainage and clearance work. In some regions mosquito flights of 6 kilometers, with *A. elutus* as the mosquito, are mentioned.

Usually there is a rise of benign tertian malaria in June and July and then a decline, and a marked rise of malignant tertian malaria in October and November. In 1926 the amount of benign tertian malaria was less than usual in June and July, but instead of decreasing subsequently it increased steadily until it reached its maximum in November. The difference in malaria incidence between 1925 and 1926 is ascribed to abnormally heavy breeding in uncontrolled areas during 1926 and to an influx of mosquitoes from these areas into the controlled areas.

Water supplies.—Due to deficient supply of pure water in Jerusalem, contaminated surface supplies were resorted to after chlorination. The supply of water varied from 50,000 to 230,000 gallons per day. A large number of villages improved their water supplies.

Sanitary engineer's section.—The activities of this section included supervision of plans of sanitary arrangements of Government buildings; new public establishments; drainage, sewage disposal, water supply, and malaria-control works; and house sanitation and plumbing. This section acts in an advisory capacity to all municipal authorities; maintains supervision over sanitary services, submitting recommendations regarding financial provisions for these services; specifies the technical requirements in matters affecting water supply, house drainage, sewerage and town planning; and controls conditions for licensing food and drink establishments.

Sewage disposal.—Tests made on raw sewage from Jerusalem subjected to a few hours, sedimentation indicated that the addition of not less than 30 p. p. m. of chlorine in the form of bleaching powder would deodorize the sewage, which had the following composition in p. p. m.: Free ammonia, 650; albuminoid am-

monia, 140; total organic nitrogen, 210; oxygen absorbed (3 hours at 37° C.), 1,010; chlorine, 2,120; suspended matter, 4,850.

Ventilation Experiments in the Moffat Tunnel. G. E. McElroy and C. A. Betts. *Engineering News-Record*, vol. 99, No. 24, December 15, 1927, pp. 956–959. (Abstract by Leonard Greenburg.)

The Moffat tunnel pierces the Continental Divide in Colorado. Prior to the completion of this tunnel it was found necessary to prepare specifications for the fans and ventilating equipment necessary so that the tunnel might be used by steam locomotives. The tunnel is single track, approximately 32,250 feet in length, and has an average cross section of 400 square feet. One-half of the tunnel will be provided with heavy timber or steel lining while the remaining half is of rock construction.

In order to determine the requirements for mechanical ventilation it was necessary to estimate the volume of flow and the necessary pressure in order to circulate this quantity of air through the tunnel. The primary purpose of the ventilation is to dilute and remove the noxious gases produced by coal in the locomotives, and the second purpose is to reduce the high temperatures which would ordinarily be found in the locomotive engine cab. It was estimated that the maximum quality of air required for dilution to 5 parts of carbon monoxide per 10,000 of air would be approximately 360,000 cubic feet per minute.

To determine the pressure required to force the air through the tunnel way, tests were conducted to determine the friction factor, and this was found to average 0.0000000005. The resistance of the clear tunnel was calculated to be 5.03 inches of water and, likewise, the resistance of the fan connection was found to be 0.02 inch of water, and for a train moving at a speed of 10 miles per hour against the flow, the resistance was found to be 1.31 inches of water, yielding a total of 6.36 inches of pressure required.

Due to the difference in elevation between the two ends of the tunnel the barometric pressures are not the same, and it was determined that there would be a strong draft of air from west to east during the winter season and a variable and reversing draft during the remainder of the year. Natural draft pressures play an important part in this problem and increase the maximum demand on the ventilation equipment, since during the winter season the fan must act against strong adverse natural draft. Experimental determinations of friction factors in the uncompleted tunnel were made in order to estimate the tunnel resistance. Interferences were frequent, because tunneling operations were still in progress. For this reason but 20 per cent of the observations escaped interference.

The determination of friction factors involves the simultaneous measurement of air flow and the difference in static pressure between the two ends of the section under test. The air velocity measurements were made with calibrated anemometers. Static pressure observations were made by means of the Bureau of Mines static tube with a Wahlen gauge. Good agreement of average results was secured and the average value of the factor was found to be 0.000000007 for velocities ranging from 57 to 80 feet a minute in the rock section of the tunnel. In the timbered section the average friction factor was found to be 0.0000000053. In a second timbered section of the Pioneer tunnel (a separate portion of the Moffat tunnel) tests of air velocities of from 250 to 700 feet a minute gave a friction factor of 0.0000000052, and at 171 feet a minute the factor was found to be 0.0000000073.

The authors point out that more data are needed on the interrelated effects of area, low velocity flow, and timber spacing as related to friction factors.

Development of Water Treatment at Indianapolis. Harry E. Jordan. *Engineering News-Record*, vol. 99, No. 19, November 10, 1927, pp. 762–764. (Abstract by D. E. Kepner.)

In 1872, when the Indianapolis Water Co. began operation, the public water supply of Indianapolis was derived from infiltration wells and galleries. This supply was later augmented by deep wells.

In 1902, three slow sand filters of 1.6 acres each, uncovered, were constructed. In 1905, central dividing walls were constructed in these, making 6 filters of 0.776 acre each, and they were then covered with flat slab roofs. The capacity of this plant was 11.7 m. g. d. following the reconstruction, but was increased to 20 m. g. d. by the addition of preliminary settling basins and by improved operation. With prechlorination this plant is now operated at the rate of 6.2 m. g. d. per acre.

In 1925, construction was started on a new rapid sand filter plant, comprising six 2 m. g. d. units with a twin coagulation basin of 6-hour total retention capacity. It has several new and interesting features, including two separate perforated pipe collecting systems for each filter unit, hydrometer and orifice-controlled alum solution application, very complete operating tables with baked enamel panels, slate tops, filtered water turbidity indicators, etc.

The filtered water turbidity, averaging 0.17 p. p. m. and never exceeding 0.3 p. p. m., and other operating results of the new plant are very gratifying.

The Problem of Rural Water Supplies. James J. Paterson. *The Journal of State Medicine*, vol. 35, No. 9, September, 1927, pp. 535–540. (Abstract by L. M. Fisher.)

The Public Health (Water) Act of 1878 provides that rural sanitary authorities shall require a sufficient water supply for every occupied dwelling; shall keep houses not so supplied from being occupied; and shall make periodical inspections. The cost of providing such a supply shall not exceed a capital sum the interest on which at 5 per cent per annum exceeds 3 pence per week. No standards of purity or adequacy can be set. Local health authorities may require cesspools to meet certain requirements, but have no authority over wells.

Private water companies are given exclusive rights in certain areas, but can not be made to supply everybody in the area if it is not profitable.

The remedy suggested is a rural water board with adequate powers, such as the Metropolitan Water Board or the Thames Conservancy Board, which have jurisdiction over the entire watersheds.

Rural Water Supplies—The Advantages of Decentralization. D. T. Worger. *The Surveyor*, vol. 72, No. 1870, November 25, 1927, pp. 513–514. (Abstract by C. C. Ruchhoft.)

The Bruston patent autopneumatic water supply system, which, briefly, consists of an automatically controlled gas engine or electric motor and a pressure tank, is recommended in decentralized units for use in rural districts where the expense of a centralized water supply system is prohibitive. The advantages of such a system are illustrated in the case of a rural district which contained 25 small parishes varying in population from less than 100 to 1,000 and having a total population of 8,439. This district may be divided into four groups of villages, two groups to be served by one pumping station and the other two groups to be served by one pumping station each. Comparison of costs for such a decentralization system for the above district with a centralized system was favorable toward the decentralized system.

Refuse Disposal in England. Anon. *Public Works*, vol. 58, No. 12, December, 1927, pp. 453–454. (Abstract by A. S. Bedell.)

This article is a summary of a section of the 1925–26 report of the Ministry of Health of England. It is pointed out that the returns from the questionnaire

are not entirely satisfactory, owing to differences in methods of accounting and in misinterpretation of the questions.

The returns from 79 towns, representing a population of 12,600,000, are tabulated in the report. Mixed collection of garbage, ashes, and rubbish is practiced in England and the average quantity collected for all towns was 1.66 pounds per capita per day, or 606 pounds per year. The average net expenditure, including depreciation and renewal charges, per ton for collection was $2.27; for disposal $1.06, or the cost per capita per annum was 65 cents for collection and 28 cents for disposal.

As to the method of disposal, 15 of the municipalities used incineration alone, and 42 incineration combined with one of the other methods. Fourteen used dumping on land alone and 34 used dumping in combination with some other method. Five used dumping at sea alone, and 3 in combination with some other method. Twelve used separation in combination with some other method, and 8 used pulverization combined with some other method. One reported land reclamation in connection with incineration and dumping. Average costs, including depreciation and renewals, were: Dumping at sea $2.24, ranging from $1.70 to $2.72; dumping on land $2.30, ranging from $1.06 to $3.85; incineration $3.70, ranging from $2.33 to $5.58.

Cleansing. W. Weaver. *The Surveyor*, vol. 72, No. 1872, December 9, 1927, p. 579. (Abstract by H. W. Streeter.)

The causes of present high yield of house refuse are: (a) Thriftlessness; (b) poor design of ranges and fire grates in older houses; (c) waste of coal fuels, where coal is cheap or of low grade; (d) inclusion, in some instances, of excrement with refuse; (e) seasonal variation in amount produced; (f) climatic conditions influencing yield of refuse. The quantity of house refuse varies greatly, but averages about 18 hundredweight per day per 1,000 people. If suitable precautions were taken in homes, 40 per cent of the refuse would be preventable, effecting a saving, in Great Britain, of 20,000,000 pounds.

Measures for increasing the amount of home destruction of refuse are discussed, including (a) installation of double bins as public property, with separation of combustible from noncombustible portions at home, and (b) payment of a bonus to householders attaining a prescribed standard. Methods for dealing with seasonable variations in refuse also are suggested.

The Treatment of Municipal Offal by Fermentation in Closed Cells. Jean Bordas. *Ann. d'hyg publ. industr. et soc.*, vol. 5, No. 3, 1927, pp. 142–150. Translation of an abstract by Kamman in *Zentralblatt fur die gesamte Hygiene*, vol. 15, No. 11 12, August 10, 1927, pp. 496–497. (Tr. by J. K. Hoskins.)

The Beccari system is used in many Italian cities, Florence, Naples, Bologna, Carrara, Novarra, for treating stable manure. The plant consists of closed chambers of about 5 cubic meters capacity, in which the manure undergoes fermentation for about 60 days. Of the evolved gases, ammonia, being the greatest, is recovered in absorption towers by means of iron sulphate and phosphate of lime. The temperature rises to from 70° to 75° C., by this method of fermentation. Nitrogen losses are also reduced to a minimum. Similar treatment of municipal organic wastes requires only 40 days. A disadvantage of treating this latter material in this way is that approximately 50 per cent of it is not fermentable.

DEATHS DURING WEEK ENDED MARCH 3, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended March 3, 1928, and corresponding week of 1927. (From the Weekly Health Index, March 8, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended Mar. 3, 1928	Corresponding week, 1927
Policies in force	70, 380, 930	66, 911, 607
Number of death claims	15, 679	13, 415
Death claims per 1,000 policies in force, annual rate	11. 6	10. 5

Deaths from all causes in certain large cities of the United States during the week ended March 3, 1928, infant mortality, annual death rate, and comparison with corresponding week of 1927. (From the Weekly Health Index, March 8, 1928, issued by the Bureau of the Census, Department of Commerce)

Nebraska	75

PLAGUE IN SANTA CRUZ COUNTY, CALIF.

A case of bubonic plague occurred at Santa Cruz, Santa Cruz County, Calif., January 23, 1928. The case was reported as suspected tularaemia by the attending physician, diagnosed clinically as plague, and diagnosis confirmed by bacteriological examinations, February 7 and 8, 1928.

Steps are being taken for intensive rodent-control work, including squirrel and rat extermination in the vicinity of Santa Cruz. The plague-control measures contemplate a 5-mile rodent-free zone.

The last case of human plague in Santa Cruz County occurred in July, 1922, and plague has not been reported in rodents from that county since September 27, 1922.

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 101 cities reporting cases used in the following table are situated n all parts of the country, and have an estimated aggregate population of more than 31,650,000. The estimated population of the 95 ities reporting deaths is more than 30,960,000. The estimated exectancy is based on the experience of the last nine years, excluding pidemics.

Weeks ended February 25, 1928, and February 26, 1927

	1928	1927	Estimated expectancy

City reports for week ended February 25, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended February 25, 1928, compared with those for a like period ended February 26, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below:

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended February 11, 1928.—The following report for the week ended February 11, 1928, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Aden.—Aden.
India.—Bassein, Bombay, Moulmein, Rangoon.
Dutch East Indies.—Makassar.
Straits Settlements.—Singapore.

CHOLERA

India.—Calcutta, Madras, Negapatam, Rangoon.
Straits Settlements.—Singapore.
Siam.—Bangkok.
French Indo-China.—Saigon.

SMALLPOX

Ceylon.—Colombo.
India.—Bassein, Bombay, Calcutta, Madras, Moulmein, Negapatam, Rangoon, Vizagapatam.
French India.—Pondicherry.
Dutch East Indies.—Belawan-Deli.
China.—Shanghai.
Kwantung.—Dairen.
Manchuria.—Mukden.

ARABIA

Aden—Further relative to plague—February 8, 1928.—Information received under date of February 8, 1928, shows a total of 152 cases of plague at Aden, Arabia, with 74 deaths, from the date of reported outbreak, January 17, 1928. It was stated that the area of prevalence had not greatly increased.

AZORES

Plague—January 22–February 11, 1928.—During the period January 22 to February 11, 1928, five cases of plague with three deaths were reported in the Azores Islands. Of these, one case with one death occurred at Livramento, and four cases with two deaths at Rabo de Peixe and San Vicente.

BARBADOS

Malaria—1927.—During the month of October, 1927, malaria was found to be present in one Parish of the Island of Barbados, British West Indies, with rapid spread. At the close of the year 1,000 cases were estimated as present in the island, with 20 fatalities occurring among infants and persons of advanced years.

Measures to prevent spread.—Measures to eliminate the anopheline mosquito were enforced and efforts made to improve the living conditions of the laboring classes.

BRAZIL

Porto Alegre—Plague.—Information has been received under date of March 6, 1928, of the occurrence of two cases of plague at Porto Alegre, Brazil. The cases were stated to have been found in the prison.

CANADA

Provinces—Communicable diseases—Week ended February 25, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended February 25, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Influenza	41			2				43
Lethargic encephalitis				1				1
Poliomyelitis		1					1	2
Smallpox				51		8	3	62
Typhoid fever	4		14	10	1	2	2	33

Quebec Province—Communicable diseases—Week ended February 25, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended February 25, 1928, as follows:

Disease	Cases	Disease	Cases
Chicken pox	33	Scarlet fever	115
Diphtheria	67	Smallpox	13
German measles	11	Tuberculosis	58
Influenza	7	Typhoid fever	14
Measles	251	Whooping cough	26

CANARY ISLANDS

Plague, bubonic—Las Palmas—Year 1927.—Bubonic plague was reported as occurring at Las Palmas, Canary Islands, during the year 1927 as follows:

Date of notice	Cases	Deaths	Remarks
Jan. 13	1		
Feb. 23	1		
Oct. 11	4		Reported in Isleta Zone.
Nov. 25	1		
Dec. 5	2	1	Pneumonic; in Isleta Zone
Dec. 16	1		
Dec. 19	1	1	
Dec. 27	1		Reported in Isleta Zone.

Deaths from certain diseases—Las Palmas—Year 1927.—Deaths from certain diseases were reported from Las Palmas, Canary Islands, for the year 1927, as follows:

	Deaths		Deaths
Bronchitis	18	Puerperal septicemia	5
Cancer	49	Syphilis	19
Diarrhea and enteritis	267	Tuberculosis (pulmonary)	149
Diarrhea and enteritis (under 2 years)	23	Tuberculosis (all other forms)	42
Diphtheria	7	Typhoid fever	9
Heart disease	157	Whooping cough	14
Influenza	1	Other communicable diseases	12
Pneumonia	105	Other diseases of the respiratory organs	26

Population: 66,461, census of 1920.

Santa Cruz de Teneriffe—Plague—January 16, 1928.—The occurrence of a fatal case of plague was reported January 16, 1928, at Santa Cruz de Teneriffe, Canary Islands.

CUBA

Habana—Communicable diseases—February, 1928.—During the month of February, 1928, communicable diseases were reported in the city of Habana, Cuba, as follows:

Disease	New cases	Deaths	Remaining under treatment	Disease	New cases	Deaths	Remaining under treatment
Chicken pox	50		45	Measles	5		6
Diphtheria	9	3	1	Paratyphoid fever		1	
Leprosy			18	Scarlet fever	11		7
Malaria [1]	14	2	3	Typhoid fever [1]	19	3	33

[1] Many of these cases from the interior.

EGYPT

Plague—Suez—District of Manfalut—January 29–February 4, 1928.—During the week ended February 4, 1928, four cases of plague were reported in Egypt, of which three cases were reported at Suez and one case in the district of Manfalut.

Summary—January 1–February 4, 1928.—During the period January 1 to February 4, 1928, 6 cases of plague were reported in Egypt, as compared with 13 cases reported for the corresponding period of the year 1927.

GREAT BRITAIN

Open-air school installed—Liverpool.—Information has been received under date of February 10, 1928, of the opening of a free open-air school at Liverpool, England. The school is stated to be the largest open-air school yet erected. It comprises two units built around a central court, which is laid out as a flower garden. The classrooms are situated on the ground floor, the upper part of the building being allotted to administrative uses and library. The buildings are equipped with hot-water heating and are lighted mainly by skylights. Classrooms measure 24 by 20 feet, and each room may be thrown wide open to the air on two sides. There are three

assembly halls. The playgrounds allow an average of 120 feet to each child. The installation of the school is of special interest in view of the prevalence of pulmonary tuberculosis in the community, especially among the poorer classes.

JAPAN

Dysentery—Tokyo, city and prefecture—January 1–28, 1928.—During the period January 1 to 28, 1928, dysentery was reported at Tokyo, Japan, as follows: Tokyo city, cases, 54; deaths, 23; Tokyo Prefecture, outside the city, cases, 74; deaths, 35. Population: City, 1,995,567; prefecture, 2,489,577.

LATVIA

Communicable diseases—December, 1927.—During the month of December, 1927, communicable diseases were reported in the Republic of Latvia, as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	2	Poliomyelitis	1
Diphtheria	27	Puerperal fever	2
Erysipelas	12	Scarlet fever	193
Influenza	23	Tetanus	1
Lethargic encephalitis	2	Trachoma	21
Measles	305	Typhoid fever	73
Mumps	7	Whooping cough	18

Population: 1,950,000.

MALTA

Communicable diseases—December, 1927.—During the month of December, 1927, communicable diseases were reported in the island of Malta, as follows:

Disease	Cases	Disease	Cases
Bronchopneumonia	5	Puerperal fever	2
Chicken pox	16	Scarlet fever	2
Diphtheria	2	Trachoma	29
Erysipelas	2	Tuberculosis	13
Influenza	6	Typhoid fever	48
Malta fever (undulant)	42	Whooping cough	1
Pneumonia	2		

Population, estimated, civil, 227,440.

MEXICO

Atotonilco—Further relative to smallpox outbreak[1]*—Vaccination.*—According to information received under date of February 29, 1928, the outbreak of smallpox at Atotonilco, State of Jalisco, Mexico, was under control, few new cases being reported. Indigent patients were being treated in lazarettoes. More than 14,000 persons were stated to have been vaccinated.

SWEDEN

Goteborg—Vital statistics, 1927.—According to statistics prepared by the Goteborg Medical Association, the total number of cases of

[1] Public Health Reports, Mar. 9, 1928, p. 586.

sickness reported by the district physicians during the year 1927 was 14,326, or 6.2 cases for every 100 inhabitants. In the year 1926 the average per 100 inhabitants was 4.4. In 1925, however, the average was 6.4 cases, and a comparison of the figures for the five-year period 1922–1926 shows that the frequency of cases of sickness during 1927 was about normal.

During 1927, 293 cases of diphtheria were reported, an increase over the preceding year of 140 per cent. Scarlet fever accounted for 290 cases and typhoid and paratyphoid fever for 26 cases. The latter figure is the lowest during the past 30 years. In 1925 there were reported 134 cases of diphtheria, 305 cases of scarlet fever, and 143 cases of typhoid and paratyphoid fever.

As compared with the year 1926, the number of cases of influenza increased 150 per cent. An outbreak of measles occurred during 1927, the number of cases reported being 1,286. In 1926 only 4 cases of measles occurred.

The number of deaths reported during the year 1927 was 2,290, or 9.9 for every 1,000 inhabitants. This was an increase of 10 per cent over the figures for the year 1926, which showed the lowest mortality figures recorded for a number of years.

Four hundred and fifty-eight deaths were due to diseases of the heart and blood vessels, while 327 deaths were caused by tuberculosis. Cancer caused 241 deaths, and deaths due to influenza totaled 92, an increase of 185 per cent, as compared with the preceding year. Diphtheria caused 11 deaths.

UNION OF SOUTH AFRICA

Plague—Smallpox—Typhus fever—January 15–21, 1928.—During the week ended January 21, 1928, a fatal case of plague was reported in Cape Province, Union of South Africa. The case occurred in a European and on a farm. During the same period smallpox was reported on two farms in Wodehouse District, Cape Province. Fresh outbreaks of typhus fever were reported for the same period in the Cape Province, occurring at 8 localities in 5 districts.

During the month of December, 1927, 83 cases of typhus fever with 15 deaths were reported in the native population of the Union of South Africa, of which 70 cases with 13 deaths occurred in the Cape Province and 13 cases, 2 deaths, in the Province of Natal. In the European population, one case of typhus fever occurred in Natal and two cases in the Cape Province.

East London—Typhoid fever—January 8–28, 1928.—During the three weeks ended January 28, 1928, 56 cases of typhoid fever with 5 deaths were reported at East London, Union of South Africa. The infection was stated to have been introduced from country districts. The occurrence was in the native population.

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following table must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

Prevalence of Smallpox in the United States
Studies on the Blacktongue Preventive in Yeast

UNITED STATES
GOVERNMENT PRINTING OFFICE
WASHINGTON
1928

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

PUBLIC HEALTH REPORTS

VOL. 43 MARCH 23, 1928 NO. 12

PREVALENCE OF SMALLPOX IN THE UNITED STATES

The reports indicate that smallpox is more prevalent in the United States than it was at this time last year or in 1926. For the week ended March 10, 1928, 42 States reported 1,161 cases of smallpox. For the corresponding week of 1927 these States reported 876 cases, and in 1926 they reported 864 cases for the week.

In 1925 the peak of the smallpox curve was reached about the middle of January; in 1926 the greatest number of cases was reported during the second week of February, and in 1927 the peak came after the middle of March. Some decrease in the incidence of smallpox is to be expected, but health officers should be constantly on the alert.

A FURTHER STUDY OF EXPERIMENTAL BLACKTONGUE WITH SPECIAL REFERENCE TO THE BLACKTONGUE PREVENTIVE IN YEAST

By JOSEPH GOLDBERGER and G. A. WHEELER, *Surgeons*, and R. D. LILLIE and L. M. ROGERS, *Passed Assistant Surgeons, United States Public Health Service*

CONTENTS

In a previous communication, Goldberger and Wheeler (1) presented some of the results of a study of the problem of an experimental animal for pellagra. They reported the production in the dog, by feeding pellagra-producing diets, of a condition considered by them to be identical with a spontaneously occurring canine disease known as blacktongue or Stuttgart dog epizootic. The similarity

of this experimental disease to human pellagra was pointed out, and was considered so striking as to be well-nigh conclusive of the identity of the two conditions. This view was supported, they believed, by the suggestion of a common etiology indicated by the successful production of the condition (blacktongue) in the dog by feeding with pellagra-producing diets. In the present paper we desire to report some further results of the same study.

METHODS

Our methods of housing, caring for, and feeding the experimental animals have been described in a preceding communication (1). It may be noted that the experimental ration was offered each animal once a day and, as a rule, freshly prepared. The amount offered was, in general, all that the dog would eat. At first, to insure this, the attempt was made to offer an excess; but in order to minimize waste this practice was, after a time, modified so that, except for a young growing animal, only enough food for the maintenance of normal body weight was offered. The animals were weighed once a week. It may be here recalled, too, that it has been our practice to use our dogs repeatedly Depending on the purpose of the experiment, the animal was or was not reconditioned by a period of stock diet feeding between successive experiments, for which purpose our stock diet No 156 (1) was the one most frequently used. In what follows, details of this nature will be noted in connection with the presentation of the pertinent parts of the history of each experimental animal. The diagnostic criteria of experimental blacktongue have been presented in a preceding article (1). Here we will say only that the earliest distinctive buccal lesions are a vivid red injection of the floor of the mouth or an erythema of the mucosa of the upper lip in the form of bilaterally symmetrical patches or both.

BLACKTONGUE-PRODUCING POTENCY OF A BASIC EXPERIMENTAL DIET AND OF CERTAIN OF ITS MODIFICATIONS

The composition of the diet with which Goldberger and Wheeler (1) first successfully induced experimental blacktongue is shown in Table 1. This diet was constructed as a somewhat simplified replica of the type of diet found associated with, and, unless suitably supplemented, believed to be responsible for, the occurrence of pellagra. After a number of modifications of the diet shown in Table 1 had been tested, the diet No. 123, shown in Table 2, was constructed and subsequently used as the basic blacktongue-producing diet in many of our experiments. It seems desirable, therefore, to summarize our experience with this (together with certain of its modifications) as a blacktongue-producing diet. This is done in experiments 1, 2, 3, and 4.

Basic Diet No. 123

EXPERIMENT 1

The blacktongue-producing potency of diet No. 123 (Table 2) has been tested in a considerable number of animals and under various conditions. We shall consider here only those tests, however, that were carried out either in animals after a period of reconditioning following a previous experiment and thus presumably in normal condition, or in such as were not previously subjected to experiment and were not known to have ever suffered from blacktongue. Such tests were performed in a total of 14 dogs, the significant details relating to each of which are as follows:

Dog 13.—Male. Acquired April 7, 1923, between which date and November 18, 1926, served in several experiments and suffered seven attacks of experimental blacktongue, the latest of which began July 31, 1925. Was on stock diet No. 156 for reconditioning from November 18 to December 8, 1926.

December 8, 1926: In good condition; weight, 10.1 kilograms; begins test diet No. 123.

On January 25, 1927, at the end of a period of 48 days, noted the first signs of blacktongue,[1] an injection of the floor of the mouth. Weight 9.4 kilograms. Confirmatory evidence of blacktongue noted on February 10, 1927. Course of the attack was remittent or relapsing in character, accompanied by self-imposed partial starvation. Killed with illuminating gas April 28, 1927.

Dog. 14.—Male. Acquired April 7, 1923. Between that date and September 25, 1923, served in two experiments and suffered a relapsing attack of blacktongue beginning May 18, 1923. On stock diet No. 34C, for reconditioning, from September 25 to October 16, 1923.

October 16, 1923: In good condition; weight, 9.3 kilograms; begins test diet No. 123.

On October 30, 1923, at the end of a period of 14 days noted the first signs of blacktongue, an injection of the floor of the mouth and a patch of redness on the mucosa of the upper lip opposite the base of the canine tooth on each side. Weight, 9.2 kilograms. Further history not relevant.

Dog 15.—Male. Acquired April 14, 1923. Between that date and September 25, 1923, served in two experiments and suffered a relapsing attack of blacktongue beginning August 7, 1923. On stock diet No. 34C, for reconditioning, from September 25 to October 16, 1923.

October 16, 1923: In good condition; weight, 9.4 kilograms; begins test diet No. 123.

On October 27, 1923, at the end of a period of 11 days, noted the first signs of blacktongue, an injection of the floor of the mouth and slight reddening of the mucosa of the upper lip. Weight, 9.3 kilograms. Further history not relevant.

Dog 50.—Male. Acquired September 25, 1923. On stock diet No. 34C to October 16, 1923.

October 16, 1923: In good condition; weight, 9 kilograms; begins test diet No. 123.

On October 27, 1923, at the end of a period of 11 days, noted the first signs of blacktongue, a definite reddening of the floor of the mouth. Weight, 8.8 kilograms. Further history not relevant.

[1] The experimental disease has been described in a preceding report (1).

Dog 51.—Bitch. Acquired September 25, 1923. On stock diet No. 34C to October 18, 1923.

October 18, 1923: In good condition; weight, 7.8 kilograms; begins test diet No. 123.

On October 30, 1923, at end of a period of 12 days, noted first signs of blacktongue, an injection of the floor of the mouth. Weight, 7.8 kilograms. Further history not relevant.

Dog 52.—Bitch. Acquired September 25, 1923. On a miscellaneous stock diet to October 22, 1923.

October 22, 1923: In good condition; weight, 8.5 kilograms; begins test diet No. 123.

On November 27, 1923, at the end of a period of 36 days, noted the first signs of blacktongue, an injection of the floor of the mouth. Weight, 8.5 kilograms. Further history not relevant.

Dog 53.—Bitch. Acquired September 25. 1923. On a miscellaneous stock diet to October 22, 1923.

October 22, 1923: In good condition; weight, 5.7 kilograms; begins test diet No. 123.

November 20, 1923: Weight, 5.8 kilograms.

On November 27, 1923, at the end of a period of 36 days, noted the first signs of blacktongue, an injection of the floor of the mouth and of the mucosa of the cheeks. Further history not relevant.

Dog 54.—Bitch. Acquired September 25, 1923. On a miscellaneous stock diet to October 22, 1923.

October 22, 1923: In good condition; weight, 6.2 kilograms; begins test diet No. 123.

On November 28, 1923, at end of a period of 37 days, noted the first signs of blacktongue, an injection of the floor of the mouth. Weight, 6.7 kilograms. Further history not relevant.

Dog 57.—Male. Acquired September 25, 1923. On stock diet No. 34C to October 16, 1923.

October 16, 1923: In good condition; weight, 7.7 kilograms; begins test diet No. 123.

On November 2, 1923, at the end of a period of 17 days, noted the first signs of blacktongue, an injection of the floor of the mouth. Weight, 8.8 kilograms. Further history not relevant.

Dog 58.—Bitch. Acquired September 27, 1923. On stock diet No. 34C to October 16, 1923.

October 16, 1923: In good condition; weight, 13. 5 kilograms; begins test diet No. 123.

On November 1, 1923, at the end of a period of 16 days, noted the first signs of blacktongue, an injection of the floor of the mouth. Weight, 14.3 kilograms. Further history not relevant.

Dog 79.—Bitch. Acquired June 9, 1924. On stock diet No. 156 to December 16, 1924, during which period was bred and whelped a litter of five pups which were successfully weaned.

December 16, 1924: In good condition; weight, 5.3 kilograms; begins test diet No. 123.

January 27, 1925: Weight, 5.5 kilograms.

On February 7, 1925, at the end of a period of 53 days, noted the first signs of blacktongue, a reddening of the floor of the mouth. Weight, 5.4 kilograms. Further history not relevant.

Dog 81.—Male. Acquired October 13, 1924. On stock diet No. 156 to November 21, 1924.

November 21, 1924: In good condition; begins test diet No. 123.

November 25, 1924: Weight, 9.4 kilograms.

On December 27, 1924, at the end of a period of 36 days, noted the first signs of blacktongue, a reddening of the floor of the mouth and of the mucosa of the cheeks. Weight, 10.4 kilograms. Further history not relevant.

Dog 82.—Bitch. Acquired October 13, 1924. On stock diet No. 156 to November 21, 1924.

November 21, 1924: In good condition; weight 10.7 kilograms; begins test diet No. 123.

On December 23, 1924, at the end of a period of 32 days, noted the first signs of blacktongue, reddened bands on mucosa of the upper lip on each side; reddening of mucosa of the cheeks, reddening of the floor of the mouth. Weight 11.5 kilograms.

Treated and used in a study of tomato juice from January 3, 1925, to November 18, 1926, during which period she had an attack of blacktongue beginning March 8, 1925.

On stock diet No. 156 for reconditioning from November 18, 1926, to December 8, 1926. On December 7, 1926, weighed 14.8 kilograms.

December 8, 1926: In good condition; begins a second period of test diet No. 123.

December 14, 1926: Weight, 13.9 kilograms.

January 18, 1927: Weight, 13.9 kilograms.

On January 22, 1927, at the end of a period of 45 days, noted the first signs of blacktongue, reddened patches on mucosa of the upper lip in region of canine teeth of each side; reddening of mucosa of the cheek, and reddening of the floor of the mouth. A rapidly progressive attack, untreated, terminating in death January 29-30, 1927.

Dog 109.—Bitch. Acquired October 29, 1926. On stock diet No. 156 to December 8, 1926.

December 8, 1926: In good condition; weight, 7.1 kilograms; begins diet No. 123.

December 28, 1926: Weight, 7.9 kilograms

On December 30, 1926, at the end of a period of 22 days, noted the first signs of blacktongue, an injection of the floor of the mouth. The attack took a slowly progressive, remittent or relapsing course accompanied by self-imposed partial starvation; untreated, terminated in death April 20, 1927. Weight on day preceding death, 3.3 kilograms.

Thus all 14 of the test animals developed blacktongue, the first distinctive signs of which appeared within not to exceed 53 days after beginning the test diet. Allowed to take its course without therapeutic interference in two of the dogs, it ended in the death of both animals. One of the animals (dog 82) was subjected to the test during two widely separated periods and responded with blacktongue beginning at the end of 32 days in the first and at the end of 45 days in the second period.

Basic Diet No. 209

In diet No. 123 (Table 2) the principal component, quantitatively, is white corn meal, which forms 66 per cent of the weight of the dry ingredients of the ration. Since yellow corn has slightly different dietary properties from the white (richer in vitamin A (2)), it seemed desirable to determine what effect, if any, the substitution in diet

No. 123 of yellow corn meal for the white would have on the blacktongue-producing potency of that diet. Accordingly the following test was made:

EXPERIMENT 2

Six dogs, numbered 44, 52, 60, 63, 64, and 73, were each offered a suitable daily portion of diet No. 209, the composition of which is shown in Table 3. By comparison with Table 2 it may be seen that this differs from diet No. 123 only in that yellow corn meal is used instead of white. The significant facts in relation to each of the test animals are briefly as follows:

Dog 44.—Male. Whelped in the laboratory June 26, 1923. Up to July 17, 1925, served in a number of feeding experiments and suffered two attacks of blacktongue, the latest of which began December 27, 1924. On stock diet No. 156 for reconditioning from July 17, 1925, to August 11, 1925.

August 11, 1925: In good condition; weight, 12.9 kilograms; begins test diet No. 209.

On September 1, 1925, at the end of a period of 21 days, noted the first signs of blacktongue, a reddening of the mucosa of the upper lip and an injection of the floor of the mouth. Weight, 13.3 kilograms. Further history not relevant.

Dog 52.—Bitch. Acquired September 25, 1923. Between that date and July 17, 1925, served in several experiments and had four attacks of blacktongue, the latest of which began March 24, 1925. On stock diet No. 156 for reconditioning from July 17, 1925, to August 11, 1925.

August 11, 1926: In good condition; weight, 10.8 kilograms; begins test diet No. 209.

On October 6, 1926, at the end of a period of 56 days, noted the first signs of blacktongue, an injection of the floor of the mouth. Weight, 9.8 kilograms. Further history nor relevant.

Dog 60.—Male. Whelped in the laboratory November 4, 1923. Up to July 17, 1925, served in a feeding experiment and suffered an attack of blacktongue, which began July 14, 1925. On stock diet No. 156 for reconditioning from July 17, 1925, to August 11, 1925.

August 11, 1925: In good condition; weight, 7.2 kilograms; begins test diet No. 209.

On September 13, 1925, at the end of a period of 33 days, noted the first signs of blacktongue, an injection of the floor of the mouth and a flushing of the mucosa of the cheeks. Weight on September 15, 1925, 7.4 kilograms. Further history not relevant.

Dog 63.—Male. Whelped in the laboratory November 4, 1923. Up to July 17, 1925, served in two experiments and suffered two attacks of blacktongue, the later one of which began March 5, 1925. On stock diet No. 156 for reconditioning from July 17, 1925, to August 11, 1925.

August 11, 1925: In good condition; weight, 7.1 kilograms; begins test diet No. 209.

On August 29, 1925, at the end of a period of 18 days, noted the first signs of blacktongue, a reddening of the floor of the mouth. Weight, 7.5 kilograms Further history not relevant.

Dog 64.—Bitch. Whelped in the laboratory November 4, 1923. Up to July 17, 1925, had suffered one uncertain, but probable, attack of blacktongue

which was in evidence June 27, 1925. On stock diet No. 156 for reconditioning from July 17 to August 11, 1925.

August 11, 1925: In good condition; weight, 6.6 kilograms; begins test diet No. 209.

On September 12, 1925, at the end of a period of 32 days, noted first signs of blacktongue, a reddening of the faucial pillars, the pharynx, and the floor of mouth. Weight, 6.7 kilograms. Further history not relevant.

Dog 73.—Bitch. Acquired March 19, 1924. Up to July 17, 1925, suffered two uncertain, evanescent attacks of blacktongue, the second of which was in evidence July 12, 1925. On stock diet No. 156 for reconditioning from July 17 to August 11, 1925.

August 11, 1925: In good condition; weight, 10.7 kilograms; begins test diet No. 209.

On December 17, 1925, at the end of a period of 128 days, noted the first signs of blacktongue, a reddening of the mucosa of the upper lip and of that of the cheeks. Weight, 8.3 kilograms. Further history not relevant.

All six dogs developed blacktongue, the first distinctive signs of which appeared within not to exceed 56 days after beginning the test diet in five, and at the end of a period of 128 days in one of them.

It would appear, then, that the substitution of yellow for white corn meal made no significant difference in the blacktongue-producing potency of the test diet.

Basic Diet No. 195

In diet No. 123 and its modification, diet No. 209, sodium chloride and calcium carbonate are used to supplement the inorganic, "ash," constituents furnished by the other components of the ration It was thought desirable to determine what effect, if any, on the blacktongue-producing potency of diet No. 123 would be produced by the substitution of a "complete" salt mixture for the sodium chloride and the calcium carbonate. For that purpose experiment 3 was carried out.

EXPERIMENT 3

Five dogs, numbered 9, 29, 83, 84, and 85, were each offered a suitable daily portion of diet No. 195, the composition of which is shown in Table 4. As may be seen by reference to Table 2, this differs from diet No. 123 only in that the well known "complete" salt mixture of Osborne and Mendel (3) replaces the sodium chloride and calcium carbonate of the latter diet. The significant facts in relation to each of the test animals were, in brief, as follows:

Dog 9.—Male. Acquired April 1, 1923, between which date and February 28, 1925, served in a number of experiments and suffered seven attacks of blacktongue, the latest of which began February 24, 1925. On stock diet No. 156 for reconditioning from February 28 to April 1, 1925.

April 1, 1925: In good condition; weight, 12.7 kilograms; begins test diet No. 195.

On May 31, 1925, at the end of a period of 60 days, noted the first signs of blacktongue, a reddening of the mucosa of the upper lip in the region of the canine teeth of each side, and an injection of the floor of the mouth. Weight, 11.4 kilograms. Further history not relevant.

Dog 29.—Male. Acquired May 9, 1923, between which date and February 28, 1925, served in a number of experiments and suffered nine attacks of blacktongue, the latest of which began February 6, 1925. On stock diet No. 156 for reconditioning from February 28, 1925, to April 1, 1925.

April 1, 1925: In good condition; weight, 11.7 kilograms; begins diet No. 195.

On April 17, 1925, at end of a period of 16 days, noted the first signs of blacktongue, a reddening of the mucosa of the upper lip and of the floor of the mouth. Weight, 11.1 kilograms. Further history not relevant.

Dog 83.—Bitch. Acquired February 20, 1925, from which date to April 1, 1925, was on stock diet No. 156.

April 1, 1925: In good condition; weight, 6.8 kilograms; begins test diet No. 195.

On April 18, 1925, at the end of a period of 17 days, noted the first signs of blacktongue, a reddening of the floor of the mouth. Weight, 7.3 kilograms. Further history nor relevant.

Dog 84.—Male. Acquired March 2, 1925, from which date to April 1, 1925, was on stock diet No. 156.

April 1, 1925: In good condition; weight, 7.8 kilograms; begins test diet No. 195.

On April 23, at the end of a period of 22 days, noted the first signs of blacktongue, reddened patches on mucosa of the upper lip opposite the canine teeth of each side. Weight, 9.1 kilograms. Further history not relevant.

Dog 85.—Male. Acquired March 2, 1925, from which date to April 1, 1925, was on stock diet No. 156.

April 1, 1925: In good condition; weight, 6.9 kilograms; begins test diet No. 195.

On April 16, 1925, at the end of a period of 15 days, noted the first signs of blacktongue, reddening of mucosa of the upper lip, of that of the cheeks, and of the floor of the mouth. Weight, 6.8 kilograms. Further history not relevant.

All five test animals developed blacktongue, the first distinctive signs of which appeared within not to exceed 60 days after beginning the test diet.

The substitution of the "complete" salt mixture for the sodium chloride and calcium carbonate of diet No. 123 made, thus, no significant difference in its blacktongue-producing potency.

Basic Diet No. 268

Although diet No. 123 (and its modifications, No. 209 and No. 195) contains a considerable amount of protein, fully one-half of which is from casein, it was thought, nevertheless, that the biological quality of the protein mixture might, perhaps, be improved by increasing the casein component, a view that was strengthened by the results of some growth tests in rats (unpublished). It seemed desirable, therefore, to determine what effect, if any, an increase in the casein component of diet No. 123, and thus, presumably, an improvement in the biological quality of its protein, would have on its blacktongue-producing potency. Experiment 4 was accordingly carried out.

EXPERIMENT 4

Eight dogs, numbered 62, 69, and 101 to 106, inclusive, were each offered a suitable daily portion of diet No. 268, the composition of which is shown in Table 5. As may be seen, this diet differs from No. 123 (Table 2) in containing 50 per cent more casein; it differs from No. 123 also in that it contains a "complete" salt mixture in the place of sodium chloride and calcium carbonate. This experiment may be considered, therefore, as a test of the effect not only of a substantial increase in protein, but also of the use, at the same time, of a complete salt mixture on the blacktongue-producing potency of that diet.

In this connection, it may be stated that this experiment was planned to serve one other purpose—namely, to secure tissues suitable for histopathological study. Believing that diet No. 268 was more nearly complete—at least for maintenance—than No. 123 or its other modifications with respect to all known dietary essentials except the specific factor or factors related to blacktongue,[2] it was thought that animals fed with it when killed at suitable intervals would furnish tissues which might show a sequence of histopathological changes which would thus be relatable to the specific dietary defect.

The significant facts in relation to each of the test animals, except as concerns the histopathology, which will form the subject of a separate report by Dr. James Denton, are briefly as follows:

Dog 62.—Male. Whelped in the laboratory November 4, 1923. Up to May 26, 1926, had one evanescent attack of blacktongue which was in evidence March 24–27, 1925. On stock diet No. 156 May 26 to June 12, 1926.

June 12, 1926: In good condition; weight, 8.8 kilograms; begins test diet No. 268.

On June 26, 1926, at the end of a period of 14 days, killed with illuminating gas for histopathological study. He presented no signs of blacktongue. Weight, 8.6 kilograms.

Dog 69.—Male. Whelped in the laboratory November 25, 1923. Up to May 26, 1926, served in two experiments, but showed no evidence of blacktongue. On stock diet No. 156 from May 26 to June 12, 1926.

June 12, 1926: In good condition; weight, 8.8 kilograms; begins test diet No. 268.

July 27, 1926: Weight, 8.7 kilograms.

July 28, 1926, at the end of a period of 46 days, noted first signs of blacktongue, a slight injection of the floor of the mouth which became more definite on August 6, and on the following day (August 7) there was noted in addition a slight reddening of the mucosa of the cheeks and of the upper lip in the region of the canines.

Animal killed with illuminating gas for histopathological study on August 7, 1926.

Dog 101.—Male. Whelped in the laboratory December 9, 1925, and reared on stock diet No. 156.

[2] The dog does not seem to require the antiscorbutic. It is probable that workers who have reported scorbutic signs in dogs were dealing with some other condition, at times, at least, with blacktongue.

June 12, 1926: In good condition; weight, 7.7 kilograms; begins test diet No. 268.

On July 10, 1926, at the end of a period of 28 days, noted first signs of blacktongue, an injection of the floor of the mouth. Weight, 7.9 kilograms. Attack slowly progressed. Animal killed with illuminating gas for histopathological study on August 7, 1926.

Dog 102.—Male. Whelped in the laboratory December 9, 1925. Reared on stock diet No. 156.

June 12, 1926: In good condition; begins test diet No. 268.

June 15: Weight, 6.10 kilograms.

July 6, 1926: Weight, 6.7 kilograms.

On July 10, 1926, at the end of a period of 28 days, noted first signs of blacktongue, an injection of the floor of the mouth. Attack progressed rapidly. Animal killed with illuminating gas for histopathological study on July 20, 1926.

Dog 103.—Male. Whelped in the laboratory December 9, 1925. Reared on stock diet No. 156.

June 12, 1926: In good condition; begins test diet No. 268,

June 15: Weight, 6.7 kilograms.

July 6, 1926: Weight, 6.4 kilograms.

On July 10, 1926, at the end of a period of 28 days, noted first signs of blacktongue, an injection of the floor of the mouth. Attack was progressive with remissions. Animal killed for histopathological study August 7, 1926.

Dog 104.—Bitch. Whelped in the laboratory December 9, 1925. Reared on stock diet No. 156.

June 12, 1926: In good condition; begins test diet No. 268.

June 15: Weight, 5.7 kilograms.

On July 6, 1926, at the end of a period of 24 days, noted first signs of blacktongue, a reddening of the floor of the mouth, of the faucial pillars, and of the mucosa of the upper lip. Weight, 5.6 kilograms. Animal killed for histopathological study July 10, 1926.

Dog. 105.—Bitch. Whelped in the laboratory December 9, 1925. Reared on stock diet No. 156.

June 12, 1926: In good condition; begins test diet No. 268.

June 15: Weight, 4.9 kilograms.

On July 15, 1926, at the end of a period of 33 days, noted first signs of blacktongue, an injection of the floor of the mouth. Weight, 5.2 kilograms. Attack mild, relapsing. Animal killed August 7, 1926, for histopathological study.

Dog 106.—Bitch. Whelped in the laboratory December 9, 1925. Reared on stock diet No. 156.

June 12, 1926: In good condition; begins test diet No. 268.

June 15: Weight, 4.3 kilograms.

On June 26, 1926, at the end of a period of 14 days, killed for histopathological study. Had presented no signs of blacktongue. Weight, 4.5 kilograms.

Of the eight test animals, two were killed at the end of a test period of 14 days for the purpose of histopathological study. Neither animal had shown any evidence of blacktongue. The period of observation was so brief that these two animals can not properly be considered in appraising the blacktongue-producing potency of the diet. The remaining six animals all developed blacktongue, the first distinctive signs of which appeared within a period of not to exceed 46 days.

It would appear, then, that the modification of diet No. 123 represented by a substantial increase in the protein combined with the

use of "complete" salt mixture was without significant effect on the blacktongue-producing potency of that diet as judged by the attack rate and duration of the feeding period before the appearance of the first distinctive signs of the disease.

In the foregoing series of tests of the pellagra-producing potency of diet No. 123 and its modifications, a total of 33 dogs were used as test animals, and blacktongue was induced in all but two of them. The two that escaped were the two that were killed at the end of a feeding period of 14 days for the purpose of histopathological study. Disregarding these as not having had a full opportunity for the development of the disease, blacktongue was induced in every one of the other 31 test animals. In each of two of these the disease was induced on two separate occasions, so that 33 separate attacks of blacktongue were induced in the 31 animals under consideration in this series of experiments. These 33 attacks developed at the end of feeding periods that varied between 11 and 128 days in duration, but only one of the attacks developed at the end of a period of over 61 days.[3]

THE BLACKTONGUE PREVENTIVE

Dried Brewers' Yeast

It may be recalled that Goldberger and Wheeler's first success in experimentally inducing blacktongue was with a diet that differed from that previously tried without success by Goldberger and Lake in that it included no milk and was not supplemented with yeast (1). The difference in outcome led us to suspect that this might be related to the difference in the diets used. There was already reason to believe that milk possessed pellagra-preventive properties (4) (5) and thus, possibly, also blacktongue-preventive properties; but, as the amount of milk contained in the diet tested by Goldberger and Lake was very small, it seemed improbable that their failure was attributable, at least to an important degree, to the milk. Up to this time we had had no suspicion that yeast might possess pellagra-preventive properties; but in seeking for the explanation of the difference in results under consideration it seemed much more likely that, if Goldberger and Lake's failure was due to the preventive action of either food, this failure was due to the action of the yeast rather than to that of the milk. Reasoning thus, it was decided to test this view; and after some preliminary trials which it seems superfluous to detail, the following experiments were performed:

EXPERIMENT 5

In this test of the blacktongue-preventive action of yeast a commercial dried brewery yeast[4] was used. It was incorporated in

[3] In harmony with this is the additional experience with this basic diet which appears incidentally in connection with some of the experiments with yeast presented in the following section.

[4] Secured from the Harris Laboratories, Tuckahoe, N. Y.

diet No. 155, the composition of which is shown in Table 6, or was fed separately in gelatine capsules as a supplement to basic diet No. 123. Comparing diet No. 155 (Table 6) with diet No. 123 (Table 2) it will be seen that, so far as it is possible to judge, yeast-containing test diet No. 155 differs from basic blacktongue-producing diet No. 123 significantly only in that 5 per cent of the weight of the solids of the former consists of dried yeast.

Five animals, dogs 15, 30, 35, 46, and 50, were used in this experiment. The essential facts pertaining to each of the test animals are presented in the following:

Dog 15.—Male. Acquired April 14, 1923. By reference to experiment 1 it will be seen that this dog developed an attack of blacktongue on diet No. 123, the first signs of which were noted on October 27, 1923. On October 30 treatment was begun by supplementing diet No. 123 with 5.4 grams (approximately 1 per cent of the dry ingredients of diet No. 123) of the dry brewery yeast. Notwithstanding this, however, a relapse of the signs of blacktongue appeared November 24, 1923. Accordingly, on November 26 the amount of yeast theretofore included in diet No. 123 was doubled. On December 27, 1923, a small further increase in the yeast was made, and on March 11, 1924, a still further increase was made which, after slight compensatory adjustment, made diet No. 155.

The evidence of the relapse noted on November 24, 1923, faded in a few days and thereafter to November 21, 1924, the dog continued in good condition without presenting recognizable evidence of blacktongue.

On November 21, 1924, yeast-containing test diet No. 155 was discontinued and basic test diet No. 123 begun.

On December 25, 1924, or 34 days after discontinuing the yeast-containing diet, there were noted the first signs of blacktongue, a reddening of the floor of the mouth. The attack, relapsing and mild, at first slowly progressed and by February 27, 1925, was fully developed and grave. The dog now had a temperature of 40 2° C. On the latter date treatment was begun with a daily dose of 20 grams of yeast in gelatine capsules administered apart from basic diet No. 123, which continued to be offered. The animal began to refuse all food on February 21 and, aside from the yeast supplement in capsules, ate nothing until March 3. Took a little food on the latter date, after which he ate well and the signs of the attack rapidly cleared up. By March 7 virtually all evidence of the attack had disappeared and by the end of the month the dog had recovered his normal weight, 9.8 kilograms.

On March 5, 1925, the daily dose of yeast was reduced to 10 grams. This dose (approximately 1 gram per kilogram of normal body weight) was calculated as about equal to the amount that would be ingested if the yeast-containing test diet No. 155 were offered in the place of basic diet No. 123 which the animal was receiving. Thus supplemented, diet No. 123 was continued to June 19, 1925 (a period of 106 days), without the return of any signs of blacktongue.

Thus dog 15 first recovered from an attack of blacktongue on a yeast-supplemented diet, then, during a period of 255 days while on yeast-containing test diet No. 155, remained in good condition and without any signs of blacktongue. The withdrawal of the yeast-containing diet was followed, at the end of 34 days, by the appearance of the beginning signs of blacktongue which progressed to a grave

attack. Treated with yeast this attack rapidly cleared up and the animal's condition returned to normal and remained so during a further period of 104 days, at the end of which time the experiment was discontinued.

Dog 30.—Male. Acquired August 1, 1923, between which date and October 29, 1923, served in two experiments and suffered two mild attacks of blacktongue. Between October 29, 1923, and March 11, 1924, was subjected to some preliminary tests of yeast.

March 11, 1924: In good condition; weighs 11.4 kilograms; begins test diet No. 155.

February 24, 1925: In good condition; weighs 10.5 kilograms.

On February 28, 1925, diet No. 155 was replaced by diet No. 123, supplemented with a daily dose of 18 grams of yeast separately administered in gelatine capsules. The dose of yeast thus administered was approximately the same as that ingested in the daily ration of diet No. 155, so that diet No. 123 so supplemented was essentially equivalent to diet No. 155.

May 19, 1925: This animal has now for upward of 14 months been on the yeast-containing test diet No. 155 or its equivalent basic diet No. 123 supplemented with yeast. The dog has shown no recognizable evidence of blacktongue at any time during this period. He has been and is in good condition; weighs 10.7 kilograms.

Effective to-day the yeast supplement to basic diet No. 123 is discontinued.

On July 2, 1925, or 44 days after discontinuing the yeast, there were noted the first signs of an attack of blacktongue, erythematous patches on the mucosa of the upper lip in the region of the canine teeth. The further history of this animal belongs to another experiment.

Dog 35.—Bitch. Acquired August 6, 1923, between which date and March 11, 1924, served in a number of experiments including a preliminary test of yeast and suffered three attacks of blacktongue, the latest of which began December 22, 1923.

March 11, 1924: In good condition; weighs 5.8 kilograms. Begins test diet No. 155.

On March 16, 1924, the animal was found to have developed an ulcerative, infective stomatitis. Very little or none of the ration was eaten between March 14 and March 26. Beginning March 20 and thereafter daily until March 26 the dog was given a dose of 12 grams of yeast in gelatine capsules. Beginning March 26 the food consumption began to improve, and by March 30 the ulcerative stomatitis had cleared up.

April 1, 1924: Eating moderately well; mouth is normal in appearance; weighs 5.3 kilograms.

November 21, 1924: In good condition; weighs 6.9 kilograms. Has presented no recognizable evidence of blacktongue during the period of 255 days since beginning yeast-containing diet No. 155.

Effective to-day diet No. 155 is discontinued and basic diet No. 123 is begun.

On December 20, 1924, at the end of a period of 29 days on the basic diet without any yeast, there were noted the first signs of an attack of blacktongue, a reddening of the mucosa of the floor of the mouth and of that of the anterior faucial pillars.

Mild and relapsing at first, the attack slowly progressed and gained in severity. The temperature of the dog was found to have risen somewhat above normal (39.6° C.) on February 20; it reached 40° the next day, and 40.5° on February 22. At this time treatment consisting of the daily administration of 15 grams of yeast,

was begun and was continued to February 25—four days—but without perceptible effect. The dog died of blacktongue February 26, 1925.

Dog 46.—Male. Acquired August 17, 1923, between which date and March 11, 1924, served in a number of experiments including a preliminary test of yeast, and suffered three attacks of blacktongue, the latest of which began February 19, 1924.

March 11, 1924: The signs of the attack of blacktongue which began February 19, 1924, have subsided without treatment. Weighs 5 kilograms. Begins test diet No. 155.

February 28, 1925: In good condition. Has presented no recognizable evidence of blacktongue during the period of 354 days since beginning yeast-containing diet No. 155.

Effective to-day diet No. 155 is discontinued and basic diet No. 123 is begun.

On March 26, 1925, at the end of a period of 26 days, there were noted the first signs of an attack of blacktongue, an erythematous patch on the mucosa of the upper lip on each side in the region of the canine teeth and a reddening of the mucosa of the floor of the mouth.

At first mild and intermittent in its course the attack became progressively more severe and led to the death of the animal on April 28, 1925. Treatment was not attempted.

Dog 50.—Male. Acquired September 25, 1923. Developed an attack of blacktongue which began October 27, 1923, in a test of basic diet No. 123. (See experiment 1.) As a part of a preliminary study, treatment of the attack with yeast was undertaken. It was begun October 29, 1923, and continued with doses increased at intervals up to March 11, 1924. During this period the attack remained mild and relapsing; the latest of the relapses appeared on February 19, 1924, and had subsided by February 25, 1924.

March 11, 1924: Presents no evidence of blacktongue; weighs 10.8 kilograms. Begins yeast-containing test diet No. 155.

February 24, 1925: In good condition; weighs 12.3 kilograms.

February 28, 1925: Diet No. 155 is replaced by basic diet No. 123 supplemented with a daily dose of 14 grams of yeast separately administered in gelatin capsules. This dose of yeast is approximately equal to the amount ingested by this animal in the daily ration of diet No. 155.

May 19, 1925: This animal has now for upward of 14 months been on yeast-containing diet No. 155 or its equivalent, basic diet No. 123 supplemented with yeast. No recognizable evidence of blacktongue has been presented by this dog at any time during this period. Is in good condition; weighs 12 kilograms. Effective to-day the yeast is withdrawn, leaving basic diet No. 123 without supplement.

On June 14, 1925, at the end of a period of 26 days without yeast, there were noted the first signs of an attack of blacktongue, a reddened patch of mucosa on the upper lip in the region of the canine teeth and a reddening of the mucosa of the floor of the mouth. The further history of this dog belongs to another experiment.

It appears, then, that so long as the test animals were fed yeast-containing test diet No. 155, or its equivalent yeast-supplemented diet No. 123 (which was done for 255 days in two, 354 days in one, and 434 days in two), none developed recognizable evidence of blacktongue; but the discontinuance of the yeast was followed within from 26 to 44 days by the appearance of blacktongue in all five of these test animals. Since, as has been shown in the first section of this

communication, the feeding of the foregoing test diet without the yeast (namely, diet No. 123) may be expected to lead to an attack of blacktongue in 100 per cent of cases within a period only very exceptionally longer than about 60 days, it would seem clearly indicated that the yeast had exercised a definite blacktongue-preventive action.

In the course of our preliminary study of the blacktongue-preventive action of yeast we gained the impression that appreciably less of the yeast than that included in test diet No. 155 might be sufficient as a preventive of blacktongue. This impression was subsequently tested, with the result shown in experiment 6.

EXPERIMENT 6

Five dogs, numbered 42, 62, 68, 69, and 76, in good physical condition, were each offered a suitable daily portion of diet No. 123AA, the composition of which is shown in Table 7. By reference to Table 2 it will be seen that diet No. 123AA is basic diet No. 123 to which 11 grams of dried yeast have been added, and that it differs from diet No. 155 (Table 6) essentially only in that it includes somewhat less than one-half the quantity of yeast contained in the latter diet. The significant facts of the experiment relating to each of the test animals are as follows:

Dog 42.—Male. Acquired June 26, 1923. Up to April 11, 1924, served in a number of experiments and suffered three attacks of blacktongue, the latest of which began April 2, 1924. On stock diet No. 156 for reconditioning from April 11 to June 24, 1924.

June 24, 1924: In good condition; weighs 11.9 kilograms. Begins test diet No. 123AA.

May 26, 1925: In good condition; weighs 11.7 kilograms. During the period of 336 days since beginning the test diet has presented no recognizable evidence of blacktongue. The experiment is discontinued

Dog 62.—Male. Whelped in the laboratory November 4, 1923, and reared and maintained on stock diets until June 24, 1924.

June 24, 1924: In good condition; weighs 7.9 kilograms. Begins test diet No. 123AA.

On March 24, 1925, a streaky redness of the mucosa of the floor of the mouth was noted which faded out in the course of the next two or three days. Other than this the animal presented no evidence of blacktongue at any time during the period of the experiment, which terminated May 26, 1925.

Dog 68.—Bitch. Whelped in the laboratory November 25, 1923. Reared and maintained on stock diets until June 24, 1924.

June 24, 1924: In good condition; weighs 8.2 kilograms. Begins test diet No. 123AA.

On September 27, 1924, a small erythematous patch was noted at about the center of the mucosa of the upper lip of each side. This faded within 48 hours. Other than this the animal presented no evidence suggestive of blacktongue at any time during the period of the experiment, which was discontinued May 26, 1925, at the end of 336 days.

Dog 69.—Male. Whelped in the laboratory November 5, 1923. Reared and maintained on stock diets until June 24, 1924.

June 24, 1924: In good condition; weighs 7.7 kilograms. Begins test diet No. 123AA.

On May 26, 1925, at the end of a period of 336 days, the experiment was discontinued. The dog was in good condition and weighed 8.3 kilograms. At no time during the duration of the experiment did he present any evidence of blacktongue.

Dog 76.—Male. Acquired June 9, 1924. Maintained on stock diet until June 24, 1924.

June 24, 1924: In good condition; weighs 8.5 kilograms. Begins test diet No. 123AA.

On May 26, 1925, at the end of a period of 336 days, when the experiment was discontinued, the dog was in good condition; weighed 9.2 kilograms. At no time during the duration of the experiment had this dog presented any recognizable evidence of blacktongue.

Thus of the five dogs fed yeast-containing diet No. 123AA during a period of 336 days—approximately 11 months—two (dogs 62 and 68) presented evanescent signs that may have been and probably were indicative of blacktongue. Since, as has been already shown, the feeding of this test diet without the yeast (that is, diet No. 123) may be expected to induce an attack of blacktongue in 100 per cent of dogs within a period very exceptionally longer than about 60 days, this result would seem to indicate that the small amount of yeast in diet 123AA (11 grams in a 2,400-caloric ration) had exercised a definite, well nigh complete, blacktongue-preventive action.

Yeast Extract Powder

The indication of the blacktongue-preventive action of yeast afforded by the foregoing experience naturally led us to inquire as to what it was in yeast that gave it this property. We began this inquiry with a test of the preventive action of a commercial preparation of what at the outset we were led to believe was the Osborne and Wakeman protein-free yeast fraction II (6), but what later we found to be simply a dried water (acidulated) extract of yeast. The results of this test are presented in experiment 7.

EXPERIMENT 7

The test of the preventive action of what, as has just been stated, proved to be a dried water extract of yeast[5] was carried out in three dogs, numbered 17, 38, and 40, by supplementing basic diet No.123 (Table 2) with a daily dose of the dried extract, as a rule separately administered in gelatin capsules, at the rate of approximately 1 gram per kilogram of body weight. The dosage used was an arbitrary one and, we judge, probably considerably in excess of minimal require-

[5] Marketed under the name "Yeast Vitamine-Harris Powder." One sample analyzed in the division of chemistry of the Hygienic Laboratory was found to contain 7.59, and another 7.14 per cent nitrogen.

ments. The significant details relating to the test in each of the animals are as follows:

Dog 17.—Bitch. Acquired April 14, 1923. Up to July 15, 1924, served in a number of experiments and suffered three attacks of blacktongue, the latest of which began June 14, 1924.

July 15, 1924: The attack of blacktongue, the first signs of which appeared June 14, has progressed and is now well marked and at a stage of moderate severity. There are present the distinctive reddening of the mucosa of the upper lip, of the cheeks, and floor of the mouth, with increase in buccal secretion and a rise in temperature to 39.8° C. Weight is 9.3 kilograms, which is fully 2 kilograms below the normal for this animal. Has eaten nothing in past 48 hours.

This attack, it may be noted, began a few days after beginning basic diet No. 123, but the onset of the attack is related to the immediately preceding experimental diet whose composition is not of interest here. Treatment with 10 grams of the yeast-extract powder is begun this day, supplementing basic diet No. 123.

July 16, 1924: Mouth is necrotic with a foul odor; drooling freely. Given a dose of 5 grams of the extract in solution by drench at 9 a. m. and 6 grams in capsules at 4 p. m.

July 20. 1924: Mouth lesions are improving. Has been receiving 10 grams of yeast-extract powder in capsules daily since July 16. Has taken a small amount of food (diet No. 123) during the past 24 hours.

July 22, 1924: Mouth lesions have practically healed. Has continued the daily dose of 10 grams of the extract. Food consumption has markedly increased during the past 48 hours. Weighs 8.8 kilograms.

July 15, 1925: This animal has now been receiving the yeast-extract powder, 10 grams daily, as a supplement to basic diet No. 123 for one year. When this supplement was begun the animal was suffering an attack of blacktongue of moderate severity. All evidence of this cleared up and no further signs suggestive of the disease have reappeared to date. The animal has thrived on diet No. 123 thus supplemented, and now weighs 13.7 kilograms.

Dog 38.—Male. Whelped in the laboratory June 26, 1923. Up to August 7, 1924, served in a number of experiments and suffered three attacks of blacktongue, a relapse of the latest of which began July 19, 1924.

August 7, 1924: The attack of blacktongue, a relapse of which began July 19, is now at a stage of considerable severity. The stomatitis is marked with salivation and foul buccal odor. The conjunctivæ are injected and there is a mucopurulent ocular discharge with photophobia. Has eaten nothing in two days and the temperature is 40°. The diet on which this attack developed is this day replaced by basic diet No.123 and treatment with a daily dose of 10 grams of dried yeast extract is begun.

August 10: The stomatitis seems better. Buccal odor continues foul, but salivation has diminished. Not eating. A dose of 10 grams of the dried yeast extract has been administered daily.

August 12: The mouth lesions have cleared up, especially those on the lip, the mucosa of which is now well-nigh normal. The eye condition appears to be of the nature of a keratitis and is not much changed. Took some food (diet No. 123) yesterday.

August 19, 1924: Buccal and ocular manifestations have now all cleared up. Eating well. Weighs 9 kilograms. Basic diet No. 123 supplemented with a daily dose of 10 grams of the powdered yeast extract is continued.

August 11, 1925: Has now been on diet No. 123 supplemented with a daily dose of 10 grams of the powdered yeast extract for a year. The animal is in good condition; weighs 11.4 kilograms. Since recovery from the attack at the height of which, on August 7, 1924, treatment was begun, there has been no return of recognizable evidence of blacktongue.

Dog 40.—Male. Whelped in the laboratory June 26, 1923. Up to May 19, 1924, served in a number of experiments and suffered three attacks of blacktongue, of which the latest began April 23, 1924.

May 19, 1924: The attack which began April 23 has now attained a stage of marked severity. The mouth is inflamed; there is an increase in buccal secretion and a foul odor. The temperature at 11 a. m. was 40.1°; at 4 p. m. it was 39.6°.

Treatment with the powdered yeast extract is begun. A solution of 15 grams in tap water is given by drench. The diet on which the attack developed is continued; food consumption is much reduced.

May 20: Condition is not notably changed. Temperature at 10 a. m. is 39.6°; at 3:45 p. m., 40.1°. Weighs 10 kilograms. A solution of 15 grams of the dried extract is given by drench.

May 22: The mouth lesions are better. Has eaten all of the food offered during the past 20 hours. Temperature at 10.10 a. m. 38.7°; at 4 p. m. 38.5°. Receiving 15 grams of the yeast extract in solution daily.

May 29: Mouth is virtually normal. Eating well. Continues the daily dose of the yeast extract which is now stirred into a portion of the food.

July 15, 1924: In good condition. Weighs 11.7 kilograms. Effective this day the diet on which the attack of blacktongue developed is replaced by No. 123, and the dose of the supplement of the powdered yeast extracts is made 12 grams and will henceforth be administered in capsules.

May 26, 1925: This animal is in good condition. Weighs 11.3 kilograms. It has been receiving a daily supplement of the yeast extract for upward of a year. Since recovery from the attack of blacktongue, at the height of which on May 19, 1924, treatment with the yeast extract was begun, there has been no return of recognizable indications of that condition to the present date.

Thus beginning in each of the three dogs with an animal which was severely attacked with blacktongue, the administration of the yeast extract powder was followed by prompt recovery and maintenance in good condition during an experimental period of approximately one year. Considered with the blacktongue-producing potency of basic diet No. 123 in mind, this result would seem clearly to indicate that the dried yeast extract served as an efficient preventive, and thus must have contained much if not all of the blacktongue-preventive factor of the yeast from which it was prepared.

Seidell's Activated Solid

Continuing our inquiry as to what it was in yeast that gave it its blacktongue-preventive action, we turned to the preparation known as Seidell's activated solid. This is a preparation of so-called vitamin B first devised by Seidell in 1916 (7). The method of preparation then proposed was improved by its author in 1922 (8) and, briefly, consists in the adsorption of the vitamins from an acidulated

aqueous extract of fresh brewery yeast by English fuller's earth. We are indebted to Doctor Seidell for a considerable batch of his preparation which we used in the beginning of the following experiment. Most of this study however, was carried out with activated solid prepared by a slight modification of Doctor Seidell's procedure (9). The modification consists essentially in the use of *dried* in the place of *fresh* brewery yeast in making the extract from which the vitamins are adsorbed. The nitrogen content of the activated solid prepared by us was about 2 per cent.

EXPERIMENT 8

The test of Seidell's activated solid was carried out in four dogs, numbered 5, 41, 89, 90. The activated solid was given as a supplement to basic diet No. 123 (Table 2) in a daily preventive dose at the rate of approximately 2 grams per kilogram of normal body weight. Unless otherwise specified, the preparation was given in gelatine capsules (veterinary No. 13) and, for preventive purposes, only once a day. In the few instances in which the study was begun with the treatment of a sick animal, the preparation was at times administered by drench in watery suspension and in broken doses. The significant details relating to each test animal are as follows:

Dog 5.—Bitch. Acquired November 8, 1921. Up to February 18, 1925, served in a number of experiments and suffered four attacks of blacktongue, the latest beginning December 23, 1924. On stock diet No. 156 for reconditioning from January 18 to February 18, 1925.

February 18, 1925: In good condition; weighs 8.7 kilograms. Begins basic diet No. 123 with a supplement of 17 grams of Seidell's activated solid daily.

February 16, 1926: Weighs 8.1 kilograms.

February 18: Has completed one year on diet No. 123 supplemented with Seidell's activated solid. Has presented no recognizable evidence of blacktongue. Is in good condition. Effective to-day the supplement of activated solid is discontinued.

March 9, 1926: Presents this morning, 19 days after the withdrawal of the supplement of activated solid, the first signs of blacktongue, a reddened patch on the mucosa of the upper lip in the region of the canines on each side and an injection of the floor of the mouth. Weighs 7.9 kilograms.

March 29, 1926: The attack of blacktongue, the first signs of which were noted March 9, was allowed to develop without therapeutic interference and ended in death some time last night.

Dog 41.—Bitch. Whelped in the laboratory June 26, 1923. Up to September 8, 1924, had served in a number of experiments and had suffered at least two attacks of blacktongue, the latest of which began August 20, 1924.

September 8, 1924: The attack of blacktongue, the first signs of which appeared on August 20, is now fully developed and of considerable severity. The stomatitis is marked. There is increased buccal secretion and there are bloody liquid stools. The temperature at 10 a. m. was 39.8°; at 2.30 p. m., 39.9°. Has eaten little or nothing during the past six days. Was given by drench, in divided doses, in the course of the day, in all 22 grams of Seidell's activated solid in watery suspension.

September 9: Condition of mouth is not notably changed. Buccal odor is fetid. Bloody evacuations continue. Temperature at 10.30 a. m., 39.7°; at 2.45 p. m., 39.8°. Weighs 7.9 kilograms. The experimental diet on which the attack developed is this day replaced by blacktongue-producing diet No. 123. Not eating. Given by drench, in divided doses, 22 grams of activated solid in watery suspension.

September 13: Very definite improvement in the buccal lesions is now appreciable. Salivation is less marked. Small, bloody, diarrheal stools continue. Temperature at 9.30 a. m., 38.5°. Given 22 grams of activated solid. Not eating.

September 16: Buccal lesions far advanced in healing. Began taking food three days ago and is now eating well. Weighs 7.4 kilograms. Has been getting 22 grams of activated solid daily.

September 19, 1924: Mouth lesions virtually completely healed. Bowel movements formed. Taking 22 grams of Seidell's activated solid daily now stirred into a portion of the ration. Eating well.

September 23, 1924: Eating well. Weighs 8 kilograms.

October 21, 1924: Administration of the activated solid in gelatin capsules begins this day.

January 21, 1925: Has continued in good condition. Eating well. Two days ago, that is on January 19, weighed 10.9 kilograms. Since recovery from the attack of blacktongue, at the height of which treatment was begun, this animal has to date presented no signs of blacktongue. Effective to-day the supply of the batch of activated solid that has been in use (supplied by Doctor Seidell) having become exhausted, a new batch comes into use and the daily dose is reduced to 11 grams, or about 1 gram per kilogram of body weight.

March 3: Weighs 10.8 kilograms.

March 4: Presents this morning, 52 days after the reduction in the daily dose of activated solid, the first signs of an attack of blacktongue, a streaky reddening of the floor of the mouth.

March 10: Weighs 10 kilograms. Food consumption greatly reduced during the past week.

March 11: The signs of blacktongue are now clearly marked but are still mild. As this development suggests that the reduced dose of activated solid is inadequate it is this day doubled, thus again making it 22 grams, which will continue to be administered in gelatin capsules as a supplement to diet No. 123.

March 16, 1925: Erythematous lesions of the mouth have faded completely; mouth is virtually normal in appearance.

March 11, 1926: During the year which has passed since the clearing up of the signs of blacktongue, which were first noted March 4, 1925, the animal has continued in good condition without any further recognizable evidence of the disease. Two days ago weighed 10.8 kilograms. Further history not relevant.

Dog 89.—Bitch. Whelped in the laboratory October 12, 1924. Reared and maintained on stock diet No. 156 to May 26, 1925.

May 26, 1925: In good condition. Weighs 4.3 kilograms. Begins basic diet No. 123 with a daily supplement of 9 grams of Seidell's activated solid in capsules.

October 30: In good conditon. Weighs 4.7 kilograms. The daily dose of activated solid is this day increased to 10 grams to correspond to the increased weight of the dog.

November 11, 1925: Continues in good condition. Weighs 4.6 kilograms. The daily dose of activated solid is reduced to 9 grams.

March 11, 1926: In good condition. Weighs 4.6 kilograms. The test of Seidell's activated solid is this day discontinued. At no time during the experimental period of nine and one-half months has this animal presented any recognizable evidence of blacktongue.

Dog 90.—Male. Whelped in the laboratory October 12, 1924. Reared and maintained on stock diet No. 156 to May 26, 1925.

May 26, 1925: In good condition. Weighs 5.9 kilograms. Begins basic diet No. 123 with a daily supplement of 12 grams of Seidell's activated solid.

July 30, 1925: In good condition. Weighs 6.7 kilograms. The daily dose of activated solid is increased to 13 grams.

March 11, 1926: In good condition. Weighs 6.8 kilograms. The test of activated solid is this day discontinued. At no time during the experimental period of nine and one-half months has this dog presented any recognizable signs of blacktongue.

The experience with Seidell's activated solid detailed in the foregoing experiment would seem clearly to indicate that this fuller's earth preparation of so-called vitamin B in a daily dose of approximately 2 grams per kilogram of body weight exercised a definite blacktongue-preventive action. We may state in this connection that a test of the plain fuller's earth has shown it to be devoid of preventive properties. The preventive action of the activated solid is therefore a property acquired by the fuller's earth in its contact with the aqueous yeast extract, presumably by adsorption.

Yeast Charcoal

Continuing our study of the blacktongue-preventive factor in yeast, we next tested its resistance to heat.

EXPERIMENT 9

Our first test of the effect of heat on the blacktongue-preventive factor in yeast was made with yeast heated to charring—charcoal. Dried brewery yeast from the same source as that used above in experiment 5 was heated in open porcelain dishes over a Bunsen flame until completely charred. One gram of the yeast yielded 0.283 gram of charcoal.[6] This charcoal was ground to a fine powder, packed in gelatine capsules of convenient size, and administered apart from the basic blacktongue-producing diet. Our experience with yeast (experiments 5 and 6) seemed to indicate that when supplementing diet No. 123 or one of its modifications, 1.25 grams per kilogram of body weight would be more than enough for preventive purposes. With this in mind, a daily dose of charcoal representing about 2 grams of the yeast per kilogram of body weight was decided on as a reasonably large therapeutic test dose when treatment is begun early in the attack. This, as will be seen, was deviated from

[6] This determination was kindly made for us by C. G. Remsburg, assistant chemist of the division of chemistry of the Hygienic Laboratory.

in but one of the test animals, which received a dose representing about 1.5 grams of the yeast per kilogram of body weight. The test animals were five dogs, numbered 29, 48, 83, 84, and 85, each in the beginning stage of an attack of blacktongue. Four of these animals had developed the attack on diet No. 195. (See experiment 3.) These were continued on that diet. The fifth animal, dog 48, had developed the attack on a diet of another character which was replaced by diet No. 123 at the outset of the present experiment.

The significant details relating to this test in each of the animals are presented briefly in the following:

Dog 29.—Male. Acquired May 9, 1923. Up to April 24, 1925, served in a number of experiments and suffered several attacks of blacktongue, the latest of which began April 17, 1925. Weight on April 21 was 11 kilograms.

April 24, 1925: The beginning buccal erythema of an attack of blacktongue noted a week ago has faded during the past two days. The diet (No. 195) on which the attack developed continues to be offered. Effective to-day, the daily administration of 6.7 grams of yeast charcoal representing approximately 27 grams, or over 2 grams per kilogram of body weight, of the yeast from which prepared, is begun.

April 25: Mucosa of upper lip and that of the floor of the mouth are again reddened.

April 28: Food consumption is at a reduced rate. Weighs 10.8 kilograms. The daily administration of 6.7 grams of yeast charcoal has been continued.

April 29: In addition to the reddening of the upper lip and of the floor of the mouth, the mucosa of the cheeks is now reddened.

May 1: Tends to regurgitate or vomit the capsules of charcoal; with a view of preventing this, some of the food will from now on be forcibly fed in conjunction with the charcoal.

May 5: The buccal lesions have become more pronounced. There is now a patch of superficial necrosis on the mucosa of the left cheek. Weighs 10.4 kilograms. Temperature is 38.6°.

May 12: Weight is 9.4 kilograms.

May 19: The buccal lesions which had become fairly marked have greatly improved during the past three or four days during which food consumption has been excellent. Weighs 9.7 kilograms.

May 25: During the past four days the mouth lesions have flared up again and are quite well marked to-day. The yeast charcoal in a daily dose of 6.7 grams has been regularly administered since April 24. No beneficial effect being appreciable, the charcoal is this day replaced by a daily dose of 22 grams of some of the same yeast as that from which the charcoal was prepared.

June 4: During the past four days the buccal lesions, which had become quite well marked, have rapidly improved so that to-day the condition of the mouth is virtually normal.

June 18: Eating well and gaining in weight. Two days ago weighed 11.1 kilograms. No further evidence of blacktongue. Effective to-day the daily dose of brewery yeast which has been 22 grams is reduced to 10 grams, or somewhat less than 1 gram per kilogram of body weight.

August 11: In good condition. Weighs 11.7 kilograms. Has been receiving the daily dose of 10 grams of brewery yeast for 54 days. Has presented no recognizable evidence of blacktongue since recovery from the attack the treatment of which with yeast charcoal had been without appreciable effect. Further history is not relevant.

Dog 48.—Bitch. Acquired August 20, 1923. Up to March 11, 1925, served in a number of experiments and suffered three attacks of blacktongue, the latest of which began March 10, 1925. Weight on March 10, 1925, was 6.2 kilograms.

March 11, 1925: Presents beginning buccal signs of an attack of blacktongue. The diet on which the attack developed is this day replaced by basic diet No. 123 and treatment is begun with a daily dose of 2 grams of yeast charcoal representing approximately 7 grams of the dried brewery yeast (or 1 gram of yeast per kilogram of body weight).

March 16: The buccal lesions after becoming more pronounced have receded slightly during the past 24 or 48 hours. No appreciable effect from the charcoal having been noted, the daily dose is this day increased to 4 grams, representing approximately 14 grams of the yeast from which prepared (corresponding to over 2 grams of yeast per kilogram of body weight).

March 17: Weighs 6.1 kilograms.

April 7: Mouth lesions of blacktongue have gone through alternating periods of recession and relapse. Eating very poorly. Weighs 5.2 kilograms. The condition is becoming complicated by self-imposed semistarvation. The charcoal is being continued.

May 16: Food refusals have become more and more pronounced. Weight has fallen off progressively. The buccal signs of blacktongue have persisted in mild degree. Moribund this morning; chloroformed. No benefit from the charcoal could be appreciated.

Dog 83.—Bitch. Acquired February 20, 1925. Served as one of the test animals of diet No. 195 (experiment 3) and developed an attack of blacktongue beginning April 18, 1925. Weight April 21, 7.5 kilograms.

April 22, 1925: The buccal signs of blacktongue are now quite definite but mild. Continues on diet No. 195. Begins treatment with a daily dose of 4 grams of yeast charcoal, representing approximately 14 grams of the yeast from which prepared and corresponding to nearly 2 grams of yeast per kilogram of body weight.

April 28: The blacktongue lesions have become somewhat more pronounced. Weighs 7.3 kilograms. The treatment with charcoal is being continued.

May 2: Buccal lesions have well-nigh completely faded. To minimize a recently developed tendency to vomit the capsules of charcoal, about 100 grams of food (diet No. 195) will, beginning this day, be forcibly fed in conjunction with the charcoal.

May 8: Lesions of blacktongue have gradually reappeared during the past two or three days.

May 16: Buccal lesions are more marked and show a superficial necrotic process. Temperature has risen to 39°.

May 17: Mouth lesions have become severe. Temperature at 10 a. m., 39.7°; at 3.30 p. m., 40.4°. Has been getting the charcoal daily without any appreciable effect. The attack now being grave, charcoal is this day replaced by 6 grams of brewery yeast.

May 21: A dose of 12 grams of yeast was administered on May 18, May 19, and May 20. That of May 20 was not retained. Found dead this morning.

Dog 84.—Male. Acquired March 2, 1925. Served as one of the test animals of diet No. 195 (experiment 3) and developed an attack of blacktongue, the first signs of which appeared on April 23.

April 23, 1925: Presents beginning signs of blacktongue, a slight reddening of the floor of the mouth and a faintly reddened patch on the mucosa of the upper lip in the region of the canines. Weighs 9.1 kilograms. Treatment is this day begun with a daily dose of 4 grams of yeast charcoal, corresponding to approximately 14 grams of the brewery yeast from which it is prepared and representing 1.5 grams of yeast per kilogram of body weight.

May 2: Mouth is normal except for faintly reddened patches on the upper lip. The administration of the charcoal continues, but a small amount (about 100 grams) of the basic diet is forcibly fed in conjunction with the charcoal to minimize a tendency to reject the charcoal.

May 23: During the month, since the treatment with charcoal commenced, the buccal signs of blacktongue have alternately receded and flared up. They are more pronounced this morning than at any time since first appearing. Food consumption has been at a progressively reduced rate. Weight four days ago was 8.5 kilograms.

There being no appreciable tendency to improvement, but, if anything, the contrary, the treatment with charcoal is this day discontinued and the daily administration of 12 grams of dried brewery yeast is begun.

May 26: Mouth lesions have cleared up. Weight is 8.3 kilograms.

August 11: In good condition. There has been no reappearance of any recognizable evidence of blacktongue. Has been receiving 12 grams of yeast daily. Weight has steadily increased and is 10 kilograms to-day. Further history not relevant.

Dog 85.—Male. Acquired March 2, 1925. Served as one of the test animals of diet No. 195 (experiment 3) and developed an attack of blacktongue beginning April 16, 1925: On April 14 weighed 5.4 kilograms.

April 16, 1925: Presents the first buccal signs of an attack of blacktongue. Begins treatment with a daily dose of 4 grams of yeast charcoal corresponding to approximately 14 grams of the yeast from which it is prepared and representing approximately 2.5 grams of yeast per kilogram of body weight.

May 2: After a gradual subsidence of the mouth lesions so that the appearance of the mouth was about normal on April 27, they reappeared on April 28 and are now more pronounced than at any time since their first appearance. There has appeared a tendency for the dog to reject the capsules of charcoal, so effective yesterday, a small amount of food is to be forcibly fed daily in conjunction with the charcoal.

August 9: The buccal lesions of blacktongue have repeatedly subsided and flared up during the past three months. They are now again well marked. Food consumption has fallen off and the weight has declined to 3.3 kilograms. Seems much emaciated and in poor general condition.

There being thus no appreciable tendency to recovery although the yeast charcoal has been daily administered, this treatment is this day discontinued and treatment with dried yeast is this day begun. A dose of 8 grams is administered to-day.

August 20: Mouth lesions have completely cleared up. Has received a daily dose of 4 grams of yeast since August 10 but because the food taking which at first improved has declined in the past three days, the dose of yeast is this day increased to 6 grams. On August 18 weighed 2.9 kilograms.

August 23: It being administratively inconvenient to continue to prepare diet No. 195, it is this day replaced with No. 123. The dose of 6 grams of yeast is continued. There is no recognizable evidence of black tongue.

September 29: Has presented no return of any recognizable evidence of blacktongue since the clearing up of the mouth lesions following the change to treatment with the yeast. Food consumption has been excellent and there has been a steady gain in weight during the past five weeks. Weight to-day is 5.8 kilograms. Further history not relevant.

Thus, in none of the five test animals was there any curative or arresting effect appreciable from the treatment with yeast heated to charring (charcoal), even though this was begun very early in or at the very onset of the attack, a failure that is all the more significant by reason of the favorable effect of treatment with the yeast itself subsequent to the failure of the charcoal treatment in three of four of the animals in which it was tried. It may be noted, too, that the dose of the yeast was relatively no greater or, indeed, was relatively less, than that of the charcoal. In the animal in which the yeast itself seemingly failed, this treatment was inaugurated at an advanced stage of the attack three days before the animal died—that is, at a stage when the chances of cure by any treatment may be expected to be greatly reduced. It would appear, therefore, that the effective factor in the brewery yeast was inactivated or destroyed by the charring heat.

P-P Activated Fuller's Earth (P-P Solid)

EXPERIMENT 10

Our next test of the effect of heat on the blacktongue-preventive factor in yeast was carried out with yeast heated in the steam autoclave for two and one-half hours at 15 pounds pressure, or, rather, with a fuller's earth preparation activated by treatment with an acidulated aqueous extract of such autoclaved yeast. The yeast was a grain medium grown, low temperature dried bakers' yeast.[7] In autoclaving, this yeast was put into glass petri dishes having a diameter of about 120 mm. and a depth of about 15 mm., and then the dishes, uncovered, were arranged on a series of screen shelves in the autoclave. On withdrawing from the autoclave the yeast was permitted to dry, after which it was ground to a powder sufficiently fine to pass a 40-mesh sieve. Next, 10 pounds of this powdered autoclaved yeast were stirred into 25 liters of tepid water containing 2.5 c. c. of glacial acetic acid (USP) and allowed to extract with repeated stirring for not less than one and one-half hours. This was then passed through a Sharples supercentrifuge four times, discarding the insoluble matter deposited in the bowl. Into the resulting effluent there were stirred 750 grams of English fuller's earth previously sifted through a 60-mesh sieve. This was kept agitated for about one hour and then the fuller's earth was separated by passing the suspension, first diluted with about an equal volume of distilled water, rapidly through the centrifuge.

[7] For which we are indebted to the Fleischmann Yeast Co., New York City.

This earth, from which the soft puttylike portion was separated and discarded, was dried in a current of warm air, then ground to pass a 60-mesh sieve. Nitrogen content of this fuller's earth preparation to which we shall refer as P–P solid (9) is about 1 per cent.

The test dose of this P–P solid was the same as that of Seidell's activated solid in experiment 8—namely, 2 grams per kilogram of body weight. It was administered in gelatin capsules once a day as a supplement to basic blacktongue-producing diet No. 123. The test animals were five dogs, numbered 15, 40, 52, 59, and 88. The significant details relating to each of these animals are briefly as follows:

Dog 15.—Male. Acquired April 14, 1923. Up to December 17, 1925, served in a number of experiments and suffered four attacks of blacktongue, the latest of which began December 25, 1924. Between February 28 and December 17, 1925, was on basic diet No. 123 supplemented with dried yeast.

December 17, 1925: In good condition. Weighs 9.6 kilograms. Continues basic diet No. 123 and begins a daily supplement of 20 grams of P–P solid, or at the rate of approximately 2 grams per kilogram of body weight.

December 21, 1926: Has completed one year on diet No. 123 supplemented with a daily dose of 20 grams of P–P solid. Has been in good condition throughout this period. Weight has varied between 9 and 10 kilograms. Now weighs 9.5 kilograms. Further history not relevant.

Dog 40.—Male. Whelped in the laboratory June 26, 1923. Up to December 17, 1925, served in a number of experiments and suffered three attacks of blacktongue, the latest of which began April 23, 1924. Between May 26 and December 17, 1925, on diet No. 123 supplemented with dried yeast.

December 17, 1925: In good condition. Weighs 11 kilograms. Continues basic diet No. 123 and begins a daily supplement of 22 grams of P–P solid, or at the rate of 2 grams per kilogram of body weight.

December 21, 1926: Has completed one year on diet No. 123 supplemented with 22 grams of P–P solid. Has been in good condition throughout, at no time presenting any recognizable evidence of blacktongue. Weighs 11 kilograms. Further history not relevant.

Dog 52.—Bitch. Acquired September 25, 1923. Up to December 17, 1925, served in a number of experiments and suffered several attacks of blacktongue, the latest of which began October 6, 1925. On stock diet No. 156 for reconditioning from December 7 to December 17, 1925.

December 17, 1925: Convalescing from the recent sharp attack of black tongue. Two days ago weighed 7 kilograms, whereas normally weighs about 10 kilograms. Begins diet No. 123 with a daily supplement of 20 grams of P–P solid, or at the rate of 2 grams per kilogram of normal body weight.

December 21, 1926: Has completed one year on diet No. 123 supplemented with a daily dose of 20 grams of P–P solid. General condition, which was poor at first, gradually improved with gain in weight. Now weighs 10. 5 kilograms. Has presented no recognizable evidence of blacktongue.

Dog 59.—Bitch. Whelped in the laboratory November 4, 1923. Reared and maintained on stock diets to February 2, 1926.

February 2, 1926: Has just weaned a litter of seven pups. Is in good condition. Weighs 5. 2 kilograms. Begins basic diet No. 123 supplemented with a daily dose of 11 grams of P–P solid, or at the rate of approximately 2 grams per kilogram of body weight.

February 2, 1927: Has completed a year on the P–P solid supplemented blacktongue-producing diet without presenting any recognizable evidence of blacktongue. Has been in good condition throughout. Weighs 5.5 kilograms.

Dog 88.—Male. Whelped in the laboratory October 12, 1924. Reared on stock diet. Up to February 2, 1926, served in one experiment and suffered an attack of blacktongue which began December 18, 1925. On stock diet No. 156 for reconditioning from December 21, 1925, to February 2, 1926.

February 2, 1926: In good condition. Weighs 5.4 kilograms. Begins basic diet No. 123 with a daily supplement of 10 grams of P–P solid.

February 2, 1927: Has completed one year on the P–P solid supplemented blacktongue-producing diet; in good condition. Has not presented any recognizable evidence of black tongue. Weighs 5.2 kilograms. Further history not relevant.

With the blacktongue-producing potency of basic diet No. 123 in mind (see experiment 1) it is clear that the P–P solid supplement has exercised complete preventive action. It follows, therefore, that the autoclaved yeast, the aqueous extract of which was used to activate the fuller's earth in the preparation of the P–P solid, retained much, if not all, of the blacktongue-preventive property of the yeast from which it was prepared. The effective factor in yeast is thus largely, if not completely, resistant to the heat of the steam autoclave at 15 pounds pressure and two and one-half hours' exposure and, under the conditions stated, is adsorbed by English fuller's earth.

Seven and One-half Hour Autoclaved Yeast

EXPERIMENT 11

This was another test of the effect of heat on the blacktongue-preventive factor in yeast. Dried bakers' yeast was exposed to the heat of the steam autoclave at 15 pounds pressure for a period three times as long as that in experiment 10—namely, seven and one-half hours. Some of this autoclaved yeast was incorporated in a diet, No. 223A, the composition of which is shown in Table 8. This diet, as may be seen by reference to Table 6, is diet No. 155, the dried brewers' yeast of which is quantitatively replaced by the 7½-hour autoclaved bakers' yeast. Test diet No. 223A was offered in suitable calorie portions to each of 5 test animals, dogs 29, 38, 84, 85, and 97. The significant details relating to each of these animals are briefly as follows:

Dog 29.—Male. Acquired May 10, 1923. Up to March 11, 1926, served in a number of experiments and suffered several attacks of blacktongue, the latest of which began April 17, 1925.

March 11, 1926: Has been receiving yeast in some form since May 25, 1925. Is in good condition. Weighed 11.7 kilograms two days ago. Begins test diet No. 223A.

March 15, 1927: In good condition. Weighs 9 kilograms. Has been receiving diet No. 223A for one year, during which period he has not presented any recognizable evidence of blacktongue.

Dog 38.—Male. Whelped in the laboratory June 26, 1923. Up to March 11, 1926, served in a number of experiments and suffered several attacks of blacktongue, a relapse of the latest of which began July 19, 1924.

March 11, 1926: Has been receiving yeast in some form since August 11, 1925. Is in good condition. Weighed 12.1 kilograms two days ago. Begins test diet No. 223A.

March 15, 1927: In good condition. Weighs 11.4 kilograms. Has been receiving diet No. 223A for one year, during which period he has presented no recognizable evidence of blacktongue.

Dog 84.—Male. Acquired March 2, 1925. Up to March 11, 1926, suffered one attack of experimental blacktongue which began April 23, 1925.

March 11, 1926: Has been receiving yeast in some form since May 23, 1925. Is in good condition Two days ago weighed 10.4 kilograms. Begins test diet No. 223A.

March 15, 1927: In good condition. Weighs 10 kilograms. Has been receiving diet No. 223A for one year but has presented no recognizable evidence of blacktongue during that period.

Dog 85.—Male. Acquired March 2, 1925. Up to March 11, 1926, suffered one attack of experimental blacktongue which began April 16, 1925.

March 11, 1926: Has been receiving yeast in some form since August 9, 1925. Is in good condition. Two days ago weight was 7.1 kilograms. Begins test diet No. 223A.

March 15, 1927: In good condition. Weighs 7 kilograms. Has been receiving diet No. 223A for one year but has presented no recognizable evidence of blacktongue during that period.

Dog 97.—Male. Acquired January 18, 1926, when about 9 weeks old and maintained on stock diet No. 156 to March 11, 1926

March 11, 1926: In good condition. Weight two days ago was 6 kilograms. Begins test diet No. 223A.

May 4, 1926: Permanent teeth have now replaced all of the milk teeth. Growth has continued. Weighs 8.5 kilograms.

March 15, 1927: Has been receiving diet No. 223A for one year. Has presented no recognizable evidence of blacktongue. Continued growth during the year. Is in good condition. Weighs 10 kilograms.

Thus, none of the five dogs developed any recognizable evidence of blacktongue during an experimental period of one year. Since test diet No. 223A differs from blacktongue-producing diet No. 123 significantly only in that the former includes some autoclaved yeast, the blacktongue-preventive action of diet No. 223A must be attributed to this yeast. It would follow, therefore, that the blacktongue-preventive factor in the yeast retained much if not all of its activity in spite of an exposure to the heat of a steam autoclave at 15 pounds pressure for seven and one-half hours.

IDENTITY OF THE BLACKTONGUE PREVENTIVE

Consideration of the results yielded, first, by the experiments with blacktongue-producing diet No. 123 and its modifications—diets No. 209, No. 195, and No. 268—and, second, by the series of experiments with yeast, leads unavoidably to the conclusion that

experimental blacktongue is due to a deficiency in diet and that yeast contains something that is capable of correcting this deficiency. It is pertinent now to inquire into the relation of this blacktongue-preventing substance in yeast to the commonly recognized dietary essentials.

Of the known dietary factors there are present in yeast in significant amount (10) only inorganic elements or "ash," protein of good biological quality, the antineuritic or vitamin F,[8] the heat-stable substance of Smith and Hendrick (11) and the pellagra-preventive (P–P) of Goldberger and Tanner (12) (13).

That the blacktongue-preventive in yeast is not the "ash" would seem to be indicated by the fact, first, that blacktongue-producing diets No. 195 and No. 268 contain what would seem to be a liberal quota of the well known "complete" salt mixture of Osborne and Mendel (3), and, second, that charred yeast, containing the ash of the yeast, when administered in what would seem to be a liberal dosage as a supplement to diet No. 195 (which, as just remarked, already includes a "complete" salt mixture) failed, as herein above shown, to reveal any evidence of a beneficial therapeutic action.

Turning to protein as possibly the effective factor we find that blacktongue-producing diet No. 268 (Table 5) includes what would seem to be a liberal amount of protein, considerably more and doubtless of a better quality than that of diet No. 123. This is likewise true of the protein of diet No. 281 (Table 9) which, as will be shown in experiment 12, when supplemented with an antineuritic preparation is also blacktongue producing. Yet, as has been seen, when diet No. 123 is supplemented with our fuller's earth activated preparation—P–P solid—which contains but about 1 per cent of nitrogen and, thus, it would seem, can at best supply but a relatively negligible amount of protein, the deficiency is corrected and blacktongue is prevented. It would seem permissible, therefore, to exclude the protein factor from consideration in the present connection.

The evidence that the effective blacktongue factor in yeast is distinct from the antineuritic vitamin is, if anything, more convincing than is the evidence just considered, that it is not identical with either the "ash" or the protein. Aside from other considerations their nonidentity is, we believe, conclusively shown by the effectiveness as a blacktongue-preventive of autoclaved yeast which, as we have elsewhere (13) already shown by tests in rats, contains but an insignificant amount, if any, of the antineuritic vitamin. Futher evidence of this as well as of the separateness of the blacktongue-preventive and protein is afforded by the results of experiment 12.

[8] Yeast both bakers' and brewers'—may vary considerably in its content of this factor. (Unpublished data.)

EXPERIMENT 12

Each of four dogs, numbered 71, 76, 86, and 87, were offered daily suitable calorie portions of diet No. 281 (Table 9). In addition, dogs 71 and 76 were given daily a supplement of our P–P solid (see experiment 10) in gelatine capsules at the rate of 2 grams per kilogram of body weight, while dogs 86 and 87 received daily a supplement of an antineuritic preparation—corn solid No. 3 [9]—at the rate of 1.25 grams per kilogram of body weight. The significant details relating to each test animal are presented in the following:

Dog 71.—Male. Whelped in the laboratory November 25, 1923. Reared on stock diets and up to October 28, 1926, served in a number of experiments and suffered an attack of blacktongue which began September 9, 1926. On stock diet No. 156 for reconditioning from October 28, 1926, to December 8, 1926. On December 7, 1926, weighed 10.3 kilograms.

December 8, 1926: In good condition. Begins diet No. 281 with a daily supplement of 21 grams of our P–P solid, separately administered in gelatine capsules.

December 21: Has been eating well. Weighs 10.4 kilograms.

December 28: Food consumption considerably diminished during the past four days. Weighs 10 kilograms.

January 4, 1927: Food consumption has continued much reduced. Weighs 8.9 kilograms.

January 11: Has taken very little food during the past week. Weighs 8 kilograms. Is much emaciated.

January 15: Eating very little. Hind legs seem weak; walks unsteadily.

January 16: Hind limbs appear stiff in walking. Knee reflex is active.

January 17: Found this morning in a semisprawling posture. During the day had repeated convulsive seizures of a tetanic type with fore legs thrust stiffly forward, hind legs semiflexed and head retracted. Mucosa of mouth normal except for some bruising of the upper lip. Temperature (rectal) at 1.25 p. m., 30.5° C. The animal has an attack which is quite like that of the "polyneuritis" frequently observed in rats on similar diets.

January 18, 1927: Died some time during the night.

Dog 76.—Male. Acquired June 9, 1924. Up to October 28, 1926, suffered one attack of blacktongue which began September 4, 1926 On stock diet No. 156 for reconditioning from October 28, 1926, to December 8, 1926. On December 7, 1926, weighed 9.7 kilograms.

December 8, 1926: In good condition. Begins diet No. 281 with a daily supplement of 21 grams of our P–P solid separately administered in gelatine capsules.

January 27, 1927: Up to December 21, 1926, food consumption was excellent. Thereafter it declined and the weight fell off. The weight two days ago was 6.8 kilograms. The 21 grams of P–P solid has been administered daily. This morning appears much emaciated and weak. In walking, hind legs seem stiff. Knee reflex present. Later in the day it became clear that this dog had "polyneuritis."

[9] This was prepared as follows: After preparing an alcoholic extract of whole corn meal as elsewhere (13) described, there was added to the extract of each 5 kilograms of corn meal 125 grams of English fuller's earth. This was then stirred for two hours, after which it was allowed to stand over night. Then the supernatant alcoholic liquor was decanted and replaced by about 2 liters of fresh 85 per cent alcohol, after which it was vigorously stirred and then allowed to settle over night. The next day the alcohol was decanted and replaced with fresh 85 per cent alcohol. After stirring, this was again allowed to stand over night, when the procedure was repeated. After the third washing the fuller's earth was transferred to a paper filter, on which it was dried in a few hours in a current of warm air. This dried activated fuller's earth, our corn solid, was then ground to pass a 60-mesh sieve and stored for use.

January 29: Down this morning, sprawling on abdomen with hind limbs abducted and flexed, fore limbs thrust forward. Tetanic spasms at intervals, but without marked opisthotonos. Mucosa of mouth normal except for traumatic patches on upper lip.

Killed with illuminating gas when seen to be dying. Ate almost nothing during last week of life.

Dog 86.—Bitch. Whelped in the laboratory October 12, 1925 Reared on stock diets. Up to October 28, 1926, suffered two doubtful attacks of blacktongue, evidence of the latter of which was present between October 25 and October 28, 1926. On stock diet No. 156 for reconditioning from October 28 1926, to December 8, 1926. On December 7, 1926 weighed 9.6 kilograms.

December 8, 1926: In good condition. Begins diet No. 281 and a daily supplement of 12 grams of our antineuritic preparation—corn solid No. 3—administered separately in gelatine capsules.

On January 8, 1927, presented a suspicious injection of the floor of the mouth which faded out two days later to reappear on January 23. On January 24 there was present on the mucosa of the upper lip of each side a faintly reddened, broken band with a more marked reddening of the floor of the mouth, constituting evidence of a mild beginning blacktongue. No signs of polyneuritis. Further history not relevant.

Dog 87.—Bitch. Acquired October 12, 1924. Up to October 28, 1926, suffered one attack of blacktongue which began September 28, 1926. On stock diet No. 156 from October 28, 1926, to December 8, 1926. On December 7, 1926, weighed 5 6 kilograms.

December 8, 1926: In good condition. Begins diet No. 281 with a daily supplement of 7 grams of corn solid No 3 separately administered in gelatine capsules.

January 24, 1927· Presents first signs of a beginning blacktongue, a reddened band on the mucosa of each cheek, reddening of the floor of the mouth and of faucial pillars The dose of 7 grams of corn solid has been regularly administered. No evidence of polyneuritis. Further history not relevant.

Thus the two dogs that received the supplement of our blacktongue-preventive preparation—P-P solid—but no known antineuritic, developed the signs of an antineuritic deficiency at the end of 39 and 50 days, respectively, but no evidence of blacktongue. In contrast, the two dogs that received the supplement of our antineuritic preparation—corn solid No. 3—but no blacktongue preventive, both developed evidence of blacktongue, one at the end of 31 days and the second at the end of 47 days, without any signs of polyneuritis during the specified periods nor, we may add, during considerably longer additional periods of observation.

These results confirm and strengthen the evidence above cited indicating that the blacktongue preventive and the antineuritic factor are separate and distinct.[10]

Thus, by a process of exclusion, we come finally to the question of the relation of the blacktongue preventive to the yeast-contained thermostable factor of Smith and Hendrick (11), and to the pellagra preventive or vitamin P-P (12) (13).

---

[10] It may be remarked, in passing, that for growth of the young rat some of both preparations must be included in a "synthetic" diet that is complete for growth excepting only the so-called vitamin B In the absence of either, even though the other be included in liberal amounts, the young rat will not grow (9).

With respect to its relation to the factor of Smith and Hendrick we may at once state that, on the basis of the available evidence (11) (13), which need not here be reviewed, the two are indistinguishable. As concerns its relation to the pellagra preventive, we have elsewhere (13) already briefly discussed this question and provisionally concluded that they were identical. Confining ourselves at this time, however, to a consideration of the evidence bearing on this question afforded by the results of the experiments recorded in the present communication alone, we have as a basis for judgment only the fact that the black-tongue preventive like the pellagra preventive is present in yeast. This association is suggestive, but, of course, by itself is far from conclusive of their identity. Taken in conjunction with the striking clinical similarity of blacktongue and pellagra, elsewhere discussed (1), and the suggestion of a common etiology indicated by the successful experimental production of the disease in the dog by feeding with a pellagra-producing diet (1), it increases somewhat the probability that blacktongue and pellagra are fundamentally identical conditions, and thus that the blacktongue preventive and the pellagra preventive, or vitamin P–P, are identical. Further evidence bearing on the question of this identity, to some of which we have elsewhere (13) already briefly referred, will be presented and considered in another communication.

SUMMARY AND CONCLUSIONS

The blacktongue-producing potency of a basic experimental diet and of three modifications was tested 33 times in 31 dogs with the production of 33 separate attacks of blacktongue. Only one of these attacks developed at the end of a period longer than 61 days.

Experimental blacktongue is due to a dietary deficiency which is capable of being corrected by something contained in yeast.

This something, or blacktongue preventive, in yeast is inactivated or destroyed by heat sufficient to char the yeast; retains its preventive potency in large measure, if not entirely, after heating in the steam autoclave at a pressure of 15 pounds for seven and one-half hours; and is adsorbed from an acidulated aqueous extract of either dried yeast or of yeast first autoclaved at a pressure of 15 pounds for two and one-half hours by English fuller's earth. It can not be identified with any of the older well-recognized dietary essentials, but is believed to be identical with the thermostable substance of Smith and Hendrick.

The blacktongue preventive and the pellagra preventive are both present in yeast. Taken in conjunction with certain other evidence pointing to the fundamental identity of blacktongue and pellagra, this association strengthens the probability that the blacktongue preventive and the pellagra preventive, or vitamin P–P, are identical.

Total nutrients		68.5	58.5	205.9
Nutrients per 1,000 calories		42.3	36.1	127.1

[1] The corn meal, farina, rice, cowpeas (previously coarsely ground), lard, and sodium chloride are stirred into a suitable amount of tap water and then cooked in a double boiler of enamel ware for about an hour and a half. At the end of this period the cooking is discontinued, the remaining ingredients are well stirred in, and the final weight of the mixture is brought to 2,000 grams by the addition of tap water with thorough stirring. 1 gram of the cooked ration represents approximately 0.8 calorie.

[2] The variety known as the California black-eyed pea.

[3] Pressed from canned tomatoes.

TABLE 2.—*Composition of experimental blacktongue-producing diet No. 128*[1]

[1] One-fifth of the starch is stirred into ten times its weight of water and cooked about ½ hour. Into the resulting jelly the remaining ingredients are stirred in the following order: Salt mixture, cottonseed oil, cod-liver oil, and the remaining starch previously mixed with the casein. The final weight is brought to 1,600 grams with water (so that 1 gram of the finished mixture represents approximately 1.5 calories). Served to dogs ad libitum.

[2] Commercial casein leached 1 week in daily changes of acidulated water, after McCollum (14).

[3] After Osborne and Mendel (3).

DEATH RATES IN A GROUP OF INSURED PERSONS

RATES FOR PRINCIPAL CAUSES OF DEATH, JANUARY, 1928

The accompanying table is taken from the Statistical Bulletin for February, 1928, issued by the Metropolitan Life Insurance Co., and presents the mortality experience of the industrial insurance department of the company, by principal causes of death, for January, 1928, as compared with January, 1927, and December, 1927. The rates are based on a strength of approximately 18,000,000 insured persons in the United States and Canada.

The death rate for January in this group of persons was 9.4 per 1,000, as compared with 9.3 for January, 1927, and with 8.7 for December, 1927.

Among the epidemic diseases of childhood, measles, scarlet fever, and diphtheria registered slightly higher rates than in January a year ago. The small increases in the rates for measles and scarlet fever are unimportant, as the rates for both years are low; but some significance attaches to the increase in the rate for diphtheria, since this disease, after registering a continuous decline for five years, showed an increase in 1927. The rates for the early months this year will therefore be watched with considerable interest.

Increased death rates as compared with January, 1927, are also shown for many of the diseases of greatest numerical importance, e. g., tuberculosis, cancer, diabetes, and the three principal "degenerative" diseases—heart disease, cerebral hemorrhage, and chronic

nephritis. The mortality from pneumonia, however, declined appreciably, and that from influenza declined slightly.

The automobile fatality situation not only fails to improve but continues to grow worse. Following the rise in mortality from automobile accidents in 1927 to the highest figure ever recorded for this group of persons, January registered the unprecedented death rate for that month of 16.1 per 100,000. The former maximum rate for January was 13.6 per 100,000, for January, 1926.

Death rates (annual basis) for principal causes per 100,000, January, 1928, as compared with January, 1927, and December, 1927

[Industrial department, Metropolitan Life Insurance Co.]

Cause of death	Rate per 100,000 lives exposed [1]			
	January 1928	December 1927	January 1927	Year 1927 [2]

COURT DECISION RELATING TO PUBLIC HEALTH [1]

Action against physician for alleged negligence in smallpox case.—(Ohio Supreme Court; Jones *v.* Stanko, Administratrix; decided January 25, 1928.) An action was brought by the defendant in error, a widow, against the plaintiff in error, a physician, to recover damages for the death of her husband, alleged to have been caused by the physician's negligence. The facts, as stated by the court, were as follows:

* * * The death of one Alexander Thompson, a neighbor of Stanko [the deceased husband], was caused by black smallpox. Dr. Jones was the sole

[1] The abstract of this decision was prepared from a copy of the decision furnished by Mr. James E. Bauman, assistant director of health of Ohio.

attending physician. He was called on Tuesday and saw the patient, Thompson, every day, and sometimes oftener than once a day, until Saturday of the same week, upon which day the patient died. It is alleged, and the evidence tends to sustain the allegation, that Mr. Stanko inquired of Dr. Jones whether Mr. Thompson was suffering from any contagious disease, and Dr. Jones assured him that Thompson was not suffering from any contagious disease, and that he, Stanko, took no risk from contagion by waiting upon Mr. Thompson in his illness. By reason of these assurances from Dr. Jones, Mr. Stanko not only waited upon Thompson prior to his death, but performed certain services with reference to his preparation for burial after death. The neighbors were in and out, doing what little they could in a friendly way to relieve the suffering of Mr. Thompson, and none of them were conscious of the fact that he was suffering from a disease that was extremely contagious, as well as infectious, to wit, black smallpox. There is no doubt that Thompson had black smallpox, and that he died as a result of that disease. It is not at all in dispute that Dr. Jones failed entirely to announce to anyone during the period mentioned that Thompson was suffering from black smallpox or any other contagious disease. It is admitted in the record that Dr. Jones failed entirely to notify the health authorities, as required by statute, of the fact that he was then treating Mr. Thompson for a contagious disease.

In the trial court a jury returned a verdict in favor of the physician. On appeal by the widow to the court of appeals, she assigned, among other errors, the refusal of the trial court to give certain requested instructions to the jury. One of the requests was, in part, as follows:

And if you also find from the preponderance of the evidence in this case that said defendant, Washington L. Jones, was the sole physician treating said Alexander Thompson during his sickness from March 17, 1925, to March 21, 1925, inclusive, and that the fact that the said Alexander Thompson was then and there suffering from the disease of smallpox would have been known to a physician possessing the requisite qualifications and applying his skill and judgment with ordinary care and diligence to the diagnosis of the said disease, it was made under such facts, if so found by you, by the provisions of the statute, just quoted, the duty of the physician in charge of said Alexander Thompson to report said disease to the health officer within whose jurisdiction such person is found, and if you further find that said defendant failed to comply with said provisions of said statute and that such failure to comply with said provisions of the statute was the proximate cause of the death of the decedent, Stephen Stanko, as by plaintiff alleged in her second amended petition herein, your verdict must be for the plaintiff.

The other requests related to the duty of the physician to discover and to make known the character of disease that his patient was suffering from, and embraced the same statement in reference to the necessary qualifications of the physician that was contained in the above-quoted request. The court of appeals reversed the trial court's judgment solely on the refusal to give the requested instructions, and the physician appealed to the supreme court. The latter court affirmed the judgment of the court of appeals, stating in part as follows:

* * * The contention of plaintiff in error is that these requests were wrong in speaking of the qualifications of the attending physician in the terms "a physician possessing the requisite qualifications," etc.

It is said that the court should have instructed the jury, in view of the evidence in the case, that Dr. Jones was only required to have the ordinary skill possessed by general practitioners in medicine in the locality of his home, and that he was not required to possess the "requisite qualifications" to diagnose and discover a case of black smallpox such as that with which Thompson died.

* * * * * * *

The only thing in dispute here is whether Dr. Jones was negligent in not discovering that this was a case of black smallpox, and in failing to give notice thereof to the public health officials and to those who were coming into the presence of Thompson and in contact with him.

We can not sustain the construction placed by counsel for Dr. Jones upon the requests to charge. The language was not intended to say, and did not say, that Dr. Jones must possess expert skill in diagnosing beyond that possessed by other doctors in general practice in that locality, or such degree of skill as insured accuracy in all cases. Counsel for Dr. Jones claim that this, in effect at least, is what these requests did say and hence the trial court was correct in refusing to give them.

We think the language used in the requests only referred to the knowledge and skill possessed by physicians in general practice, as distinguished from the knowledge and statements of laymen present, who might venture opinions on the subject with respect to which no one would be entitled to rely for his own safety. The instruction to the jury was that, in order to find Dr. Jones liable, they must find that he was one holding himself out as a general practitioner of medicine.

The law requires a man who engages in the general practice of the medical profession to be one who has educated himself to take care of the matters incident to such practice, and one of the things that he must be held to know is whether he is dealing with a disease which is dangerously contagious. If it were a defense for such practicing physician, who had failed to discover and give due notice of the presence of such a disease, to say that he had not theretofore treated a disease of that kind, and had not observed symptoms such as the patient involved manifested, the escape from the provisions of the statute would surely be marvelously easy.

It will be noted that in each one of the requests, after speaking of a physician "possessing the requisite qualifications," the request gives the degree of care that must be exercised, by stating that it must be ordinary care and skill. A physician is not the insurer of his patient, but his patient has the right to believe that one holding himself out as qualified to practice medicine has the requisite skill to deal with that subject, and when so dealing, he must exercise ordinary skill and care relative to the matter in hand. It is that, and no more, that is required by those requests numbers 11, 12, and 15, and we quite agree with the court of appeals that this language does not present reversible error in this case. Aside from the feature of the requests mentioned—a physician possessing the requisite qualifications—it is not seriously contended that these requests are erroneous. The requests as presented should have been given, and the failure to give them was clearly error prejudicial to the plaintiff in the trial court. * * *

PUBLIC HEALTH ENGINEERING ABSTRACTS

Chloro-Phenol Tastes Pervade Chicago Water Supply. Anon. *Engineering News-Record*, vol. 100, No. 3, January 19, 1928, pp. 115–116. (Abstract by W. M. Olson.)

This is a summary of particulars concerning the bad taste of Chicago's water supply during the latter part of December, compiled from a report by Doctor Bundesen, of the Sanitary District of Chicago, and from other sources.

"One of the worst periods of taste-producing pollution of water by industrial wastes at the southern end of Lake Michigan occurred December 23–30, 1927, when the water supply of Chicago and of the Indiana cities of Gary, East Chicago, Whiting, and Hammond, farther south, was rendered undrinkable. This condition affected more than 3,000,000 people, as well as numerous industries using city water in the manufacture of edible products."

The taste-producing elements were phenol and cresol compounds of chlorine caused by the reaction between tarry acid wastes from by-product coke plants and chlorine used for disinfecting the water supplies. "The amount of phenol pollution was very great, being about 60 parts per billion."

Results of investigations of the source and motion of the wastes are summarized. Prompt and efficient chlorination control measures by the municipal division of water safety control are noted. "The absorption of chlorine by the industrial wastes and sewage was exceptionally heavy and made it necessary to use relatively large quantities of this chemical to assure a safe water based on residual chlorine control." A maximum chlorine dosage of 13.6 pounds per million gallons was carried for one hour.

"Bacterial analyses of special samples collected during the emergency indicated serious contamination by sewage organisms. The chlorinated water samples, however, showed that the dangerous pollutional organisms were killed."

The Practical Utility of Bacteriologic Control of Water Supplies. Ivan C. Hall. *Journal American Water Works Association*, vol. 19, No. 1, January, 1928, pp. 69–77. (Abstract by W. L. Havens.)

Early evidence that such diseases as typhoid fever, the paratyphoids, the dysenteries, and cholera were frequently transmitted by drinking water naturally led to the hope that the detection of such bacteria in water would serve as a criterion of its potability. However, it is very rare that these organisms can be isolated directly from naturally polluted water supplies, for the reasons that (1) the relative number of these organisms is small in proportion to nonpathogenic forms, (2) their persistence in water is transitory, and (3) they lack distinguishing characteristics from the harmless species naturally present. The sanitarian has therefore become mainly interested in discovering criteria of pollution rather than in the detection and isolation of specific disease-producing organisms. These criteria may be based upon either chemical tests for chlorides, the presence of nitrogeneous compounds, or a high oxygen demand. The more direct criteria of pollution are bacterial.

Total agar plate counts may be of practical significance in determining relative amounts of pollution, in indicating the efficiency of a purification process, and in controlling the bacterial content of swimming pools. Extreme care must be used in interpreting the results of various presumptive tests for *Bact. coli* since other organisms, such as *Bact. aerogenes*, may produce similar reactions. Having identified the presence of *Bact. coli*, which may be of either human or other animal origin, it can only be assumed that the water is potentially dangerous and precautions should be taken before it is used as a source of supply. Bacterial tests must therefore be interpreted with extreme caution unless they are used for indicative purposes only.

Manganese Interference in the Orthotolidine Test for Available Chlorine. Edward S. Hopkins. Ind. Eng. Chem., vol. 19, pp. 744–6, 1927. Abstract by Edward S. Hopkins in the *Journal American Water Works Association,* vol. 18, No. 6, December, 1927, p. 763.

"Attention is called to the fact that unstable salts of manganese will oxidize orthotolidine and produce the characteristic yellow color. Entire reliance can not be placed upon this test for available chlorine if manganese is present in a water supply. The possible chemical formulae for manganese under such conditions are discussed."

Water Purity and Fish Life. W. Rushton. *The Surveyor,* vol. 72, No. 1872, December 9, 1927, p. 574. (Abstract by H. W. Streeter.)

The care taken to preserve river water for drinking purposes and the lack of attention to preserving the natual fauna and flora when the waters are required for other purposes are the main subjects of the paper.

Pure water will not support fish life, because of the absence of a suitable food supply. Also, if certain ingredients are absent, diseases, including goiter, will appear among fish. If rivers must receive effluents from various works they should not destroy the natural fish life or permit foreign growths killing natural ones.

Comparing the fish food value of water works filter beds and impounding reservoirs, slow sand filters are shown to be good places for rearing fish, but reservoirs are often deficient in fish food.

Evidence exists that waters from producer gas plants harm small streams, owing to presence of sulphur compounds and carbon monoxide in solution. Effluents from coal-washing plants and coke ovens are known to harm river waters for fish life.

Report on Electrolux Water Softener. Anon. *Journal of State Medicine of Royal Institute of Public Health,* vol. 36, No. 1, January, 1928, pp. 49–50. (Abstract by H. V. Pedersen.)

The electrolux softener used in the experiment consisted of a tinned-copper cylinder 1 foot, 8 inches high and 5 inches in diameter, containing a special kind of earth treated in a particular manner, but composed mainly of alumina and silica. Periodically the softening material must be regenerated with dissolved common salt.

The conclusions arrived at from the experiments are as follows: "(1) By analysis it is found that all the hardness is removed from the water; (2) that no deleterious ingredient could be detected in the softened water; (3) that this method of water softening is very simple, economical, and efficacious."

The Correlation Between Differential Tests for Colon Bacteria and Sanitary Quality of Water. I. M. Lewis and E. E. Pittman. *Journal American Water Works Association,* vol. 19, No. 1, January, 1928, pp. 78–92. (Abstract by W. L. Havens.)

This article describes the several methods which have been proposed for the differentiation of fecal from nonfecal colon bacteria and gives the practical limitations of the various methods, particularly in an effort to determine which of them correlates best with the sanitary quality of the water. The supplies under consideration were obtained from deep fissure springs located along the Balcones escarpment from Austin, Texas, to Del Rio. The conclusion drawn is that the citrate test is more easily and quickly applied than the methyl red and Voges-Proskauer reactions and has been shown to correlate better with the sanitary quality of the water.

The Microscopy of Drinking Water. A review by W. C. Purdy. *Journal American Water Works Association,* vol. 19, No. 1, January, 1928, pp. 93–94. (Abstract by W. L. Havens.)

This article is a review of the fourth edition of "The Microscopy of Drinking Water," by George Chandler Whipple, as revised by Gordon M. Fair and Melville C. Whipple. The new book contains much new material and is divided into two sections, one dealing with applied microscopy and the other with determinative microscopy. The essence of the book is to determine the meaning of the presence of microscopic organisms in water and the interpretation which the sanitary engineer may safely place upon his biological findings.

Laws and Regulations for Protection of Public Water Supplies. W. J. Scott. *Water Works*, vol. 65, No. 10, October, 1926, pp. 479–484. (Abstract by Harriet S. Ryan.)

This is a review of outstanding features in the water-supply conditions in New England, given in a paper presented September 15 at the forty-fifth annual convention of New England Water Works Association.

The topography and natural water resources in New England make it necessary to use but very few water supplies at the present time which can be considered sewage polluted. General conditions are such that chlorination can be regarded as a factor of safety rather than an integral part of necessary purification processes. The absence of water filtration plants and dependence mainly upon clean watersheds and storage, necessitate legal methods of protection against dangerous watershed conditions.

The existing laws and regulations are classified under ten headings, and the status of conditions is discussed under these headings. There is a wide variation in legal methods of protection of public water supplies where no great dissimilarity exists in conditions. It is shown in the discussion that the repealing of some statutes and the adoption of others would aid considerably in furnishing safe water. The immediate charge of water supplies can properly be in the hands of local officials, but the statutes should place the supervision of public water supplies under the State department of health and no new source or no change in existing sources should be constructed without the approval of that department. The statute should place with the State department of health the authority to order owners of waterworks to undertake necessary changes, with proper provisions for appeal and for financing the necessary improvements. The legislation of Ohio is quoted. The provision in the Massachusetts law, making the granting of permits discretionary with the department of public health, seems satisfactory. There should be statutory authority to take land for watershed protection by right of eminent domain, with provision for equitable settlement. The Connecticut statute concerning the construction of a reservoir near a cemetery should be amended. The Massachusetts statute, which prohibits new cemeteries on watersheds without approval State, seems desirable. The manner of cross connections should be left to the discretion of the State department of health. The Massachusetts procedure for setting up the machinery for cities and towns for emergencies is worthy of consideration.

The First Year's Operation of the Providence, R. I., Filtration Plant. Julius W. Bugbee and Elwood L. Beam. *The American City*, vol. 37, No. 6, December, 1927, pp. 731–736. (Abstract by J. B. Harrington.)

This article describes the new Scituate project of the Providence, R. I., water supply and its operation for the first year. The new project consists of a hydroelectric plant, a 37,000,000,000 gallon impounding reservoir, an influent aerator, a head house for storage and application of coagulants, a rotary mixer, two coagulating basins of 31,000,000 gallons and 94,000,000 gallons capacity, respectively, 10 rapid sand filters with a capacity of 48,000,000 gallons a day, an effluent aerator, and a chemical storage house.

The plant was placed in operation on September 30, 1926. The results obtained by varying the chemical dosage, by increasing the retention period in

the coagulating basins, by adjusting the aerators, and by changing the length and rate of filter wash are all described briefly. Bacteriological results indicate that the raw water is practically free from *B. coli* and that the final effluent is consistently negative.

Quantitative Studies of Phenols in Water Supply. W. Donaldson and R. W. Furman. *Journal American Water Works Association*, vol. 18, No. 5, November, 1927, pp. 605–620. (Abstract by C. R. Cox.)

Recent water supply studies in Toledo, Ohio, included the analyses of industrial wastes containing phenolic compounds and also a critical review of the results secured by various workers in estimating the amount of phenol in waters and in detecting the intensity of tastes produced by phenolic compounds. It was found that the Folin-Denis reagent is sensitive to 0.02 p. p. m. phenol, cresol, cresylic acid mixture, and wood creosote, and that the Fox and Gauge reagent is sensitive to 0.01 p. p. m. phenol and cresol and to 0.02 p. p. m. cresylic acid and wood creosote. It was found in the distillation of 250 c. c. portions of the samples that only 85 per cent of pure phenol was recovered in three 50 c. c. Nessler tubes. Twenty phenol wasted were sampled as they were discharged into the Maumee River, and the phenolic content ranged from 0.004 p. p. m. to 19.0 p. p. m., with an average of 1.129 p. p. m. A concentration of 37.8 p. p. m. existed in one of the wastes being discharged into Ten Mile and Swan Creeks, with an average of 7.308 p. p. m. Maximum concentrations of between zero and 0.072 p. p. m. phenol were found present in samples of water collected from Lake Erie and the Maumee River and tributaries. It was found that pure phenol when unchlorinated could be detected by the taste when present in undiluted Lake Erie water in concentrations of 25.0 p. p. m. The three cresols or their mixtures, however, gave a taste in concentrations of 0.10 to 0.30 p. p. m. After chlorination the iodoform or chloro-phenol taste was detected when phenol was present in 0.08 p. p. m. and when the cresols were present in concentrations of 0.02 p. p. m. This is in excess of the quantities which other workers have found to produce a noticeable taste; for instance, 0.002 p. p. m. phenol is reported to have produced tastes in Milwaukee. It is shown that the ratio of the minimum concentration of pure phenol and chlorine required to give a noticeable taste in filtered Maumee River water varied with the concentration. In other words, with 0.001 p. p. m. phenol, tastes were produced with 0.092 p. p. m. chlorine, whereas with 0.025 p. p. m. phenol it required 0.675 p. p. m. chlorine to produce a taste. With larger concentrations of phenol, smaller concentrations of chlorine produced tastes; for instance, 0.800 p. p. m. phenol produced a taste with 0.075 chlorine. It was concluded in the article that the sense of taste is more sensitive than the chemical procedures used in detecting phenol in water, although quantitative methods used at Toledo are justified because of the nature of the problems being studied. The discussion of this paper emphasizes the fact that the taste method has several weaknesses, namely, that the intensity of taste depends upon the concentration of chlorine, the temperature of the water, and the physical quality of the water independent of the phenolic content.

Five Years' Operation of a Rapid Sand Filtration Plant. M. C. Whipple and H. C. Chandler. *The American City*, vol. 38, No. 1, January, 1928, pp. 133–138. (Abstract by C. R. Cox.)

This article gives a comprehensive description of the new rapid sand filtration plant of Cambridge, Mass., together with a discussion of the problems of operation. Highly colored water from two sources was coagulated during the first three years with alum in basins with a detention period of 2.5 hours. The dose of alum varied between 1.15 and 1.73 g. p. g. Provisions were made to add soda ash to the raw water when necessary to provide alkalinity, although

this treatment was seldom needed. About two years ago the use of solid sodium aluminate was begun, and improved coagulation has resulted by the use of 1.0 g. p. g. of alum and 0.2 g. p. g. of sodium aluminate. This modified treatment has permitted a reduction of about 50 per cent in the soda ash dose applied to the filtered water to prevent corrosion of the distribution system, and the water in the plant is less corrosive to the equipment. A chlorine dose of 0.25 p. p. m. produces a nearly sterile final effluent.

No mixing basin is provided, and the 2.5 hours' coagulation and sedimentation period is insufficient at times. Color in stored water is easier to coagulate than fresh color from swamps in times of flood run-off. Two and one-half-inch lead piping for alum solution requires constant attention to prevent clogging. Daily flushing under pressure, weekly bleach treatment to kill *Leptothrix*, and periodic steaming are remedies in constant use. Even then, hand cleaning becomes necessary.

Filters are washed for 2½ minutes at velocities necessary to expand sand beds 30 per cent. This requires 27 inches vertical velocity at 70° F. and 20 inches at 38° F. Wash water is thus saved in winter. Water is drawn down to below sand bed before washing, to increase agitation of sand. Sand-bed shrinkage occurs in summer, although this occurs when coagulation is best and when filtered water is clear and colorless. The theory is that good floc forms dense surface mat which resists flow and is thus compressed and pulled away from walls. Beds are hand raked every 10 days. Caustic soda treatment with 0.25 per cent solution is applied twice each year to clean the sand grains.

DEATHS DURING WEEK ENDED MARCH 10, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended March 10, 1928, and corresponding week of 1927. (From the Weekly Health Index, March 14, 1928, issued by the Bureau of the Census, Department of Commerce)

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Data for 67 cities.
[4] Deaths for week ended Friday, Mar. 9, 1928.
[5] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15; Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; and Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occuring

PLAGUE-INFECTED GROUND SQUIRRELS—SANTA CRUZ, CALIF.

A report dated February 27, 1928, states that six ground squirrels shot in the outskirts of the city of Santa Cruz, Calif., have proved positive for plague. The squirrels were shot in the immediate vicinity of the place where the boy who contracted plague was engaged in trapping squirrels. (See PUBLIC HEALTH REPORTS, March 16, 1928, p. 628.)

Poisoning operations against squirrels in this vicinity are being carried out by the extensive use of thalium poisoned grain. Trapping operations directed against rats are in progress in the city of Santa Cruz, but no rat suspected of plague infection had been caught at the time of the report.

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 98 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of nearly 30,450,000. The estimated population of the 98 cities reporting deaths is more than 30,440,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended March 3, 1928, and March 5, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
43 States	1,862	1,832	
98 cities	1,008	1,062	921
Measles:			
42 States	18,713	15,408	
98 cities	6,345	5,167	
Poliomyelitis:			
43 States	43	11	

Weeks ended March 3, 1928, and March 5, 1927—Continued

	1928	1927	Estimated expectancy
Scarlet fever:			
43 States	5,246	6,247	----------
98 cities	1,723	2,451	1,406
Smallpox:			
43 States	1,150	999	----------
98 cities	101	127	135
Typhoid fever:

98 cities	54	51	38
Deaths reported			
Influenza and pneumonia:			
98 cities	1,237	1,112	----------
Smallpox:			
98 cities	1	0	----------
Charleston, W. Va.	1	0	----------

City reports for week ended March 3, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years When the reports include several epidemics, or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during non-epidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population, July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

[1] Rabies (human); 1 case and 1 death at Chicago, Ill.
[2] Typhus fever: 2 cases at Savannah, Ga.

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended March 3, 1928, compared with those for a like period ended March 5, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927 and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below:

Summary of weekly reports from cities, January 22 to February 25, 1928—Annual rates per 100,000 population compared with rates for the corresponding period of 1927 [1]

FOREIGN AND INSULAR

SMALLPOX ON VESSEL

Mombasa, British East Africa—Steamship "Khandalla"—January 14, 1928.—The steamship *Khandalla* arrived at the port of Mombasa, British East Africa, with two deck passengers infected with smallpox. The cases were landed January 14, 1928. The *Khandalla* arrived at Durban, Natal, Union of South Africa, January 25, 1928, with no history of further outbreak of smallpox on board.

THE FAR EAST

Report for the week ended February 18, 1928.—The following report for the week ended February 18, 1928, was transmitted by the Eastern Bureau of the Health Section of the Secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt.—Alexandria, Suez.
Aden Protectorate.—Aden.
India.—Bassein, Bombay, Rangoon.
Ceylon.—Colombo.
Siam.—Bangkok.
Straits Settlements.—Singapore.

CHOLERA

India.—Bombay, Calcutta, Negapatam, Rangoon.
Siam.—Bangkok.
French Indo-China.—Saigon

SMALLPOX

Aden Protectorate.—Perim.
Ceylon.—Colombo.
India.—Bombay, Calcutta, Madras, Moulmein, Negapatam, Rangoon.
French India.—Pondicherry.
Dutch East Indies.—Banjermasin, Belawan-Deli.
Straits Settlements.—Singapore.
China.—Shanghai.
Kwantung.—Dairen.
Manchuria.—Mukden.

Returns for the week ended February 18, were not received from Samarinda, Dutch East Indies, nor Vladivostok, Union of Socialist Soviet Republics.

ANGOLA

Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported in Angola as follows:

Disease	Coast District	Land Frontier	Interior	Total
Ancylostomiasis	2		5	7
Beriberi	2	6		8
Bilharzia	10		12	22
Chicken pox (including alastrim)	31		32	63
Dysentery	28	15	7	50
Erysipelas	1			1

CANADA

Provinces—Communicable diseases—Week ended March 3, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended March 3, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever					2			2
Influenza	18			11	1	5		35
Poliomyelitis				1				1
Smallpox		1		36		6	16	59
Typhoid fever	2	4	24	20	2			52

Quebec—Communicable diseases—Week ended March 3, 1928.—The Provincial Bureau of Health of Quebec reports cases of certain communicable diseases for the week ended March 3, 1928, as follows:

Disease	Cases	Disease	Cases
Chicken pox	54	Scarlet fever	104
Diphtheria	56	Smallpox	12
German measles	10	Tuberculosis	33
Influenza	8	Typhoid fever	24
Measles	300	Whooping cough	15

Sydney, Nova Scotia—Vital statistics, 1927.—The medical officer of the city of Sydney, Nova Scotia, reported 790 births and 232 deaths for the year 1927.

Communicable diseases were reported for the year as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	2	Scarlet fever	27
Chicken pox	1	Tuberculosis	60
Diphtheria	9	Typhoid fever	10
Measles	39	Venereal diseases	55
Mumps	21		

CHILE

Concepcion—Vital statistics—October-December, 1927.—During the fourth quarter of the year 1927, 806 births were reported in Concepcion, Chile, and the number of deaths registered was the same.

There were 359 deaths of infants under one year of age, giving an infant mortality of 445 per 1,000 births.

The deaths included the following:

Disease	Deaths	Disease	Deaths
Bronchial pneumonia	41	Nephritis	7
Cancer	18	Pneumonia	138
Diabetes	2	Puerperal fever	4
Diphtheria	1	Syphilis	6
Dysentery	12	Tuberculosis	114
Influenza	6	Typhoid fever	5
Measles	19	Typhus fever	1

CUBA

Malaria—July, 1926, to December, 1927.—Malaria was officially reported in the city of Santiago, the Province of Oriente (including Santiago), and the Republic of Cuba, during the 18 months from July, 1926, to December, 1927, inclusive, as follows:

Quarter	Santiago de Cuba	Oriente Province	Republic of Cuba
1926			
July to September	146	883	1,857
October to December	1,587	2,538	5,662
1927			
January to March	1,757	3,296	4,938
April to June	492	776	1,161
July to September	888	1,556	1,861
October to December	1,178	1,506	2,105

Provinces—Communicable diseases—December 25, 1927–February 11, 1928.—During the period from December 25, 1927 to February 11, 1928, cases of communicable diseases were reported from the Provinces of Cuba as follows:

Disease	Pinar del Rio	Habana	Matanzas	Santa Clara	Camaguey	Oriente	Total
Cerebrospinal meningitis		2					2
Chicken pox	26	40	11	5	3	18	103
Diphtheria	1	25	12	8	2	15	63
Malaria		56	10	5	116	365	552
Measles		13	2		20	1	36
Paratyphoid fever		3		11	4	10	28
Scarlet fever	2	7	6	1			16
Tetanus (infantile)					1	2	3
Typhoid fever	19	97	11	37	13	60	237

GERMANY

Vital statistics—January to June, 1927.—Preliminary compilations of vital statistics of Germany for the first six months of the year 1927

show 244,496 marriages, 604,018 live births, 409,643 deaths (excluding stillbirths), and 20,362 stillbirths. As compared with similar statistics for the first six months of the year 1913, there was a decrease in the birth rate of about 29 per cent, while the death rate decreased about 16 per cent.

The infant mortality rate for the six months of 1927 was about 30 per cent lower than it was for the same period in 1913.

The following table gives a comparison of the rates for the first six months of the years 1913, 1925, 1926, and 1927:

	1913	1925	1926	1927
Marriages per annum per 1,000 population:				
First quarter	6.2	5.7	5.6	6.0
Second quarter	9.0	8.7	8.5	9.5
Births per annum per 1,000 population:				
First quarter	27.2	21.9	20.4	19.2
Second quarter	26.8	21.8	20.2	19.0
Deaths per annum per 1,000 population:				
First quarter	15.9	12.6	13.0	14.5
Second quarter	15.0	12.0	11.9	11.4
Deaths of infants under 1 year of age per 1,000 live births:				
First quarter	143	110	108	111
Second quarter	147	95	99	92

GREAT BRITAIN

England and Wales—Vital statistics, 1927.—The following table, showing birth and death rates in England and Wales for the year 1927, was prepared from figures published by the Registrar General of England and Wales:

	England and Wales	107 county boroughs and great towns	155 smaller towns	London
Birth rate per 1,000	16.7	17.1	16.4	16.1
Annual death rate per 1,000:				
All causes	12.3	12.2	11.3	11.9
Diphtheria	.07	.08	.05	.09
Influenza	.57	.49	.58	.39
Measles	.09	.12	.07	.04
Scarlet fever	.01	.01	.01	.01
Smallpox	.00	.00	.00	.00
Typhoid fever	.01	.01	.01	.01
Violence	.51	.48	.41	.51
Whooping cough	.09	.10	.08	.12
Death rate per 1,000 births:				
Diarrhea and enteritis (under 2 years)	6.3	8.3	5.0	7.5
All deaths under 1 year	69	71	68	59

London is included in the 107 county boroughs and great towns. The "smaller towns" are those with populations of from 20,000 to 50,000.

HAWAII TERRITORY

Island of Hawaii—Plague—February 16, 1928.—A death from bubonic plague occurred at Kukuihaele, Island of Hawaii, on February 16, 1928.

The last previously reported case of human plague at Kukuihaele occurred August 12, 1927, and plague has not been reported in rodents in the Island of Hawaii since December 20, 1927.

JAMAICA

Smallpox (alastrim)—January 29–February 25, 1928.—During the period January 29 to February 25, 1928, five new cases of smallpox (alastrim) were reported in the Island of Jamaica outside of Kingston.

Other communicable diseases.—During the same period other diseases were reported in Jamaica as follows:

Disease	Kingston	Other localities	Disease	Kingston	Other localities
Chicken pox		20	Puerperal fever		1
Dysentery	4	13	Tuberculosis	22	33
Erysipelas		1	Typhoid fever	22	82

Population: Kingston, 62,707; Island of Jamaica, 926,000.

PORTO RICO

Fajardo, vicinity of—Smallpox unofficially reported—March 12, 1928.—Under date of March 12, 1928, smallpox in epidemic form was unofficially reported present in the vicinity of Fajardo, Porto Rico.

UNION OF SOUTH AFRICA

Cape Province—Spread of plague infection among veldt rodents—February 10, 1928.—Information received under date of February 10, 1928, indicates serious spread of plague in veldt rodents in the Cape Province, Union of South Africa, during the past few months. The spread is stated to have taken place southward from the Calvinia district into the Ceres Basin to a point about 10 miles north of Ceres, and to the westward into Namaqualand to a line about 15 miles west of Springbok and roughly parallel with the coast. The affected area was stated to include Springbok, Garies, and Nieuwerust, extending to within a few miles of Van Rhynsdorp and about 25 miles northward of the protective belt which had been cleared of rodents along the Oliphant River and the irrigation canals. The wave of infection was stated to be spreading rapidly. Indications were noted that hares, which are numerous in that area, were playing an important part in spread of the infection.

It was stated that the spread into the Ceres Basin was especially important as that area is separated from the open gerbille-infested area on the Cape Peninsular side by a mountain barrier about 3 miles wide traversed by passes. It is intended to clear these passes of rodents and to strengthen the defences within the area.

Orange Free State—Plague—January 22–28, 1928.—During the week ended January 28, 1928, two cases of plague with one death, were reported in the Sastron district, Orange Free State. The occurrence was in natives and on a farm.

Typhus fever.—Fresh outbreaks of typhus fever were reported during the week ended January 28, 1928, in the Cape Province, in the Mount Frere district and in the Kroonstad district, Orange Free State.

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, Health Section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

ASST. SURG. GEN. R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

PUBLIC HEALTH REPORTS

VOL. 43 MARCH 30, 1928 NO. 13

CURRENT WORLD PREVALENCE OF COMMUNICABLE DISEASES [1]

United States, February 12–March 10, 1928

The mortality in large cities during the first 10 weeks of 1928 has been very favorable and has followed very closely that of last year. A slight increase occurred at the end of February as was to be expected, but the seasonal rise in mortality has been unusually slight. The annual rate for 68 cities for the 10 weeks ended March 10 was 13.8 per 1,000, which is the same as for the corresponding period of 1927.

Influenza.—The cases of influenza reported by 31 States increased at the end of February and beginning of March, but not sharply enough to indicate an epidemic situation. The reported cases averaged about 1,600 weekly for the first eight weeks, and the number increased to 2,163 cases in the week ended March 3 and 2,996 cases in the week ended March 10. The incidence has been very similar to that reported a year ago. In 1927 the seasonal maximum was passed in the week ended March 12, and in 1926, when the disease was epidemic, the maximum was passed a week later.

In certain Southern States, notably in Alabama, Arkansas, and Louisiana, the reported incidence of influenza has been somewhat higher than it was a year ago; but the number of cases has shown no tendency to rise continuously for several weeks in a characteristic epidemic curve. The influenza and pneumonia death rate by weeks up to February 18 also indicates a greater prevalence of respiratory conditions in the South Central States this year than a year ago; but in the remainder of the country, the weekly mortality from those causes has varied about the level of that in 1927.

Smallpox.—The prevalence of smallpox showed no further increase in the four weeks ended March 10, when 4,465 cases were reported by 42 States as compared with 4,618 cases in the preceding four-week period; but this is approximately 1,000 more cases than were reported in the corresponding four-week period a year ago. For the most part, the incidence of the cases in different parts of the country in the

[1] From the Office of Statistical Investigations, United States Public Health Service.

four weeks ended March 10 was unchanged as compared with the incidence in the preceding weeks.[1] The outbreak in Connecticut was promptly brought under control and only 10 cases were reported in the four weeks ended March 10, as against 126 in the preceding six weeks. An increase in cases is shown in the Arizona reports; 146 cases were reported in the four weeks ended March 10 as compared with 27 cases from January 1 to February 11.

Scarlet fever.—The number of cases of scarlet fever reported each week by 41 States continued to vary around 5,000 up to the week ended March 10. The disease has been less prevalent in the current year than at the corresponding season of last year, but a little more prevalent than it was two years ago. In none of the States does the incidence suggest any epidemic situation. The period of relatively high seasonal prevalence is rather wide in the case of scarlet fever and the disease may be expected to continue at the present level for several weeks.

Diphtheria.—The number of cases of diphtheria reported weekly by 41 States has been declining since the week ended February 4; in that week 2,250 cases were reported, whereas in the week ended March 10, 1,700 cases were reported. The maximum incidence occurred a little later in the present year than in either 1926 or 1927. The incidence in the current year has not differed significantly from that in 1927, but has been somewhat higher both in January and February than in the corresponding season of 1926.

Measles.—Measles cases continued to increase during February and the first part of March, and some further increase is likely, since the seasonal decline normally does not set in until quite late in the spring. There were 33,520 cases reported by 41 States in the two weeks ended March 10, as compared with 31,775 and 26,386 cases, respectively, in the two weeks ended February 25 and February 11. The incidence is still slightly above that reported last year, as was noted in the review of last month, but the number of cases is now smaller than the total reported by the same States in corresponding weeks of 1926, which was a "measles year." The reported incidence would seem to indicate that the disease is epidemic to some extent in the current year in about one-half the States scattered throughout the country.

Poliomyelitis.—There were fewer new cases of poliomyelitis in the four weeks ended March 10 than in the preceding four weeks, but more than in the corresponding weeks of either of the two preceding years. The 35 different States which reported one or more cases during this four-week period reported a total of 147 cases; California reported the largest number, 27 cases, Massachusetts

[1] Public Health Reports, Mar. 9, 1928.

reported 13 cases, New York reported 15 cases, and Oregon reported 9 cases.

Typhoid fever.—Cases of typhoid fever declined slightly during February; 41 States reported 118 cases in the week ended March 10, as against 215 cases in the week ended February 4. The disease has been less prevalent than in either of the two preceding years in most States.

Foreign Countries [1]

No unusual epidemic situation prevailed during December or January in any of the foreign countries for which the health section of the League of Nations had received reports. As in the United States, the general mortality in European towns reflected only a normal seasonal increase. Full official information on the widespread epidemic of influenza in Japan, which has been reported in the newspapers, is not yet available.[2] The prevalence for certain epidemic diseases is summarized below, chiefly from information taken from the League of Nations' Monthly Epidemiological Report

Cholera.—Port towns in the Far East which reported any cases of cholera during the five weeks ended February 4 included only Singapore, Bangkok, Saigon and Cholon, Samarang, and five towns in British India. Calcutta, with 123 deaths in these five weeks, and Bangkok, with 55 cases in four weeks of January, are the only towns reporting more than six cases or deaths in January. In Bangkok, a definite increase in the incidence of the disease during January is indicated; only one or two cases were reported weekly during November and December, but in January the number increased gradually, and 28 cases were reported in the week ended January 28.

An increase in cholera incidence in French Indo-China occurred at the end of December. In Annam, 174 cases were reported in the first 20 days of January, as compared with 22 cases in the month of December; in Cochin-China, 165 cases were reported in the same period, as compared with 113 in December. No increase had occurred in Cambodia, Laos, or Tonkin.

In India, the incidence of cholera declined steadily during December; 2,353 deaths were reported in the week ended December 31 as against 4,835 in the week ended November 26, but the deaths were still much above the normal for the season. The late autumn outbreaks in Bengal, Assam, Bihar and Orissa, and in Madras Presidency reached a maximum toward the end of November, and the disease declined rapidly in the succeeding weeks in each of these areas.

Plague.—The outbreak of plague at Aden, which began January 9, continued to spread, and up to February 11 there had been 197 cases

---

[1] Data from the Monthly Epidemiological Report of the Health Section of the League of Nations' Secretariat, Feb. 15, 1928, supplemented by information published in the Public Health Reports

[2] See p 790. —Ed.

and 111 deaths reported. The number of cases increased each week and 89 cases were reported in the week ended February 11. One case occurred on January 19 at Baghdad, where there had been no plague since June. Five cases of plague were reported at Suez in the first five weeks of 1928, and these were the only cases reported in Egypt in this period.

No case of plague was reported in January from any Mediterranean port. Four cases were reported on the island of Teneriffe and three on the island of Las Palmas.

In Nigeria, the plague incidence in January continued lower than for several years past; 15 cases were reported in the five weeks ended February 4 as compared with 12 cases in the preceding five-week period. In the Union of South Africa, only 3 cases of plague were reported in January, all in inland districts, as compared with 6 cases in December and 9 in November.

The plague situation in India as a whole continued good in December, although there was a marked increase in cases about the middle of the month, followed by a drop to the previous level at the end of the month. The increase was due to a rapid spread of the disease in the United Provinces, as shown in the table below.

Plague cases reported in the United Provinces by two-week periods in the years 1924–1927

Year	Oct. 23–Nov. 5	Nov 6–19	Nov 20–Dec 3	Dec 4–17	Dec 18–31
1927	67	136	408	837	596
1926	60	200	312	421	285
1925	45	84	336	557	541
1924	280	316	580	783	799

The plague outbreak in the Madura district of the Madras Presidency also continued to increase in December. The plague incidence in most provinces was unusually favorable.

Since May, 1927, deaths from plague in Java have been somewhat more numerous than in 1926; the incidence remains, nevertheless, well below that of 1924 and 1925, when plague reached its greatest extension in Java. The disease continues to be most prevalent in the central part of the island; its incidence decreased in Kedu, which was the province most affected in 1926, but increased markedly in Pekalongan and Cheribon, both provinces on the northern coast.

Deaths in Java during the 20 weeks ended December 3

	1925	1926	1927
Java, total	5,683	2,599	3,342
East Java	141	14	101
Central Java	4,753	2,445	2,712
West Java	789	140	529

Plague was less prevalent in Peru in 1927 than in any year since its introduction in 1903. During the first 11 months of the year there were 188 cases and 62 deaths, as compared with 1,200 cases in 1926 and 418 cases in 1924, the previous low year. There were 14 cases and 4 deaths reported in December.

Plague incidence in Guayaquil has remained practically the same for several years. In January 4 cases were reported, and the number of cases varied from 3 to 9 a month for the preceding six months.

Two cases of plague were reported at Buenos Aires in the week ended February 11 and one each in Rosario and Santiago Province in the following week. Four cases had occurred at Rosario in January.

Yellow fever.—Yellow fever cases and deaths which were officially reported in West Africa in the past three years are shown in the accompanying table.

Yellow fever cases and deaths in West Africa, 1925–1927

Country	1925		1926		1927	
	Cases	Deaths	Cases	Deaths	Cases	Deaths
Ivory Coast	3	1	0	0	3	3
Dahomey	0	0	2	1	4	4
Upper Volta	0	0	2	2	0	0
Niger Territory	0	0	0	0	1	1

French Sudan	6	4	5	4	0	0
Gold Coast	7	4	23	13	107	41
Nigeria	21	14	11	7	3	2
French Togo	0	0	0	0	8	8

A short summary of the history of yellow fever, of the more important scientific investigations that have been carried out, and of recent epidemics is published in the February Epidemiological Report.

Smallpox.—In England and Wales the seasonal increase in smallpox cases was quite marked during January, but the number of cases reported in the four weeks ended January 28 (1,461 cases) was considerably smaller than that for the corresponding period of 1927 (2,184 cases). The disease is prevalent over a larger area in the current year than was the case a year ago, having spread to a new center in South Wales and to the Midlands and southern counties.

Smallpox cases continued to increase in the French Protectorate of Morocco; 398 cases were reported in December as against 140 in November and 81 in October. In Algeria, where smallpox was widespread during 1927, the number of cases has been declining; only 39 cases were reported in the first three weeks of 1928 as compared with 154 in the preceding three weeks. In Tunis only 3 cases occurred between November 26 and January 21.

Returns for smallpox cases in India for November and December were considerably lower in 1927 than in 1926. Bengal, southern

Assam, Orissa, and eastern Bihar had, as usual in recent years, the highest incidence.

The noteworthy decrease in the smallpox incidence and case fatality rate in Java continued throughout 1927. During the first 48 weeks of that year there were 281 cases and 8 deaths, in comparison with 5,994 cases and 1,301 deaths in 1924, 4,652 cases and 508 deaths in 1925, and 819 cases and 87 deaths in 1926. The case mortality rate was 21.7 per cent in 1924, 10.9 per cent in 1925, 10.6 per cent in 1926, and 2.8 per cent in 1927. An active vaccination campaign has been carried out in recent years.

Typhus.—The number of typhus cases reported in Europe, excluding the Union of Socialist Soviet Republics, was about the same in 1927 as in the preceding two years. In Latvia, Poland, the Kingdom of the Serbs, Croats, and Slovenes, and Greece, the incidence decreased from 1925 to 1927, but it increased at the same time in Lithuania, Rumania, and Bulgaria. Fewer cases, however, were reported in December, 1927, than in the corresponding month of any previous year in all of these countries.

TABLE 1.—*Typhus cases reported in various countries of Europe and North Africa*

Country	1924	1925	1926	1927
Estonia	43	21	24	18
Latvia	290	96	72	30
Lithuania	618	221	325	450
Poland	7,706	4,196	3,568	3,059
Czechoslovakia	44	204	167	199
Hungary	229	33	10	5
Rumania	3,312	1,892	2,355	2,893
Kingdom of the Serbs, Croats, and Slovenes	319	388	199	117
Bulgaria	197	217	238	297
Greece	866	102	68	39
Total	13,624	7,370	7,026	7,107
Egypt	1,683	1,314	966	792
Tunis	209	404	423	413
Algeria	471	540	311	889
Morocco	----------	510	559	1,053

Typhus was less prevalent in the third quarter of 1927 than during the corresponding period of 1926 in the Central Industrial and Black So l Districts of the Union of Socialist Soviet Republics as well as in the Ukraine; the incidence was slightly higher, on the other hand, in northern and eastern Russia.

There was a marked increase of typhus fever in 1927 in Algeria and Morocco. During the first four weeks of 1928, 813 cases of typhus fever were reported in French Morocco, as compared with 111 in January, 1927.

Influenza.—There is no sign of any serious influenza epidemic in the January statistics of European countries. The number of deaths

attributed to influenza in large towns of England and Wales, which had been slowly increasing in December, began to decrease after the first week of January, an unusual occurrence. The number of deaths from influenza in German towns was low during the first two weeks of January. There was a slight increase in Paris, where 23 deaths were ascribed to influenza in December and 74 deaths in January.

There were 12 deaths from influenza in December at Madrid, 13 at Milan, 7 at Lyons, 6 at Prague, and 2 at Vienna, which shows a relatively low incidence for the season.

Measles.—Measles was moderately epidemic in most European countries during the last quarter of 1927, but the incidence was nowhere higher than is normally the case during the increases which usually occur every two or three years. The incidence in the third quarter of 1927 was lower than it was during the corresponding period of 1926 only in the Union of Socialist Soviet Republics, Estonia, Poland, Bulgaria, Greece, Albania, Malta, and Spain. The indications are that in many countries the maximum of the present winter will be passed earlier than usual.

Whooping cough.—Whooping cough shows no unusual prevalence in any of the countries for which information is available. The incidence was well below the normal during the fourth quarter of 1927 in England and in Denmark.

CURRENT STATE MORTALITY STATISTICS

For the information of public health officials and others interested, the data in the following tables have been taken from the monthly mortality reports of State health departments for the latest month for which published records are available. Statistics of most communicable diseases are not included, since they are available in other tabulations in the Public Health Reports. Statistics of deaths from other causes are limited for the most part to those causes which appear in the State reports. In the case of States which publish detailed mortality reports each month, the record of only the principal groups of causes and certain important specific causes have been used.

For purposes of comparison, the mortality records for the corresponding month in a few preceding years have been compiled. The rates have been computed upon the populations as estimated for July 1 of each year represented.

These tabulations will be enlarged as the current data on mortality from additional States become available.

Homicide	5.0	4.4	....
Accidents	80.7	82.5	....

Commenting upon these statistics, the Health News said:

The health of the people of the State of New York in 1927 was exceptionally good. The total number of deaths was less than a year ago by more than 10,000, mainly because of a lessened volume of mortality from tuberculosis, pneumonia, and diseases of the heart and kidneys. The death rate (12.3 per 1,000 population) was never lower and was equaled but once in 43 years. Infant mortality (59 deaths under one year per 1,000 live births) was the lowest recorded since 1904, when these deaths were first compiled separately. Mortality from most of the diseases of childhood, with the exception of diphtheria, also showed a gratifying decrease.

With reference to the decrease in deaths from diseases of the heart, the further comment is made:

We must not, however, ascribe too much significance to this decline because the high death rate in 1926 was directly influenced by an extraneous factor—the abnormally severe weather during the first months of the year. The present death rate from diseases of the heart, with the single exception of the preceding year, is still greater than ever before.

With respect to other causes, the Health News continues:

The death rate from pneumonia declined 28 per cent and the proportion of deaths due to this cause was only 8.7 as compared with 11.1 in 100 deaths last year. Here, too, we recall the very high mortality in February, March, and April, 1926. But, unlike diseases of the heart, the death rate from pneumonia in 1927 was, with one exception, the lowest ever recorded.

Cancer, with the highest mortality on record, is now second among the causes of death. A year ago it was third, in 1917 it was fifth, and 20 years ago it was eighth—being preceded in order by pneumonia, tuberculosis, diseases of the heart, acute and chronic nephritis, diarrhea and enteritis (under 2 years), accidents and cerebral hemorrhage and apoplexy.

The death rates from nephritis, acute and chronic, and from tuberculosis, all forms, have never been lower. The decline in the tuberculosis death rate was the greatest recorded in any one year since 1921 and the 1927 rate was one-half of the rate recorded only 10 years ago. The reduction in the death rate from

accidents was less than that which occurred in the mortality from all causes and the relative importance of this group has increased somewhat, from 6.2 to 6.6 per cent.

Ohio, 1927 and 1926

The following statistics are taken from the Ohio Health News of February 15, 1928, published by the Ohio State Department of Health:

Mortality in Ohio in 1927 and 1926

Death classification by cause	1927	1926
	Annual rate per 1,000	
All causes	11.2	12.2
	Rate per 1,000 live births	
Infant mortality	63	76
	'Annual rate per 100,000	
Typhoid fever	2.70	4.49
Smallpox	.15	.01
Measles	.55	12.51
Scarlet fever	2.36	2.92
Whooping cough	4.03	10.11
Diphtheria	7.78	7.51
Influenza	22.41	39.67
Acute poliomyelitis	2.56	.68
Meningococcus meningitis	.67	.51
Rabies	.17	.09
Tuberculosis, all forms	70.82	79.09
Other epidemic, endemic, infectious diseases	16.58	19.18
Cancer, all forms	98.53	100.31
Cerebral hemorrhage	101.60	110.15
Heart diseases, all forms	203.56	201.47
Broncho pneumonia	36.42	48.08
Lobar pneumonia	44.17	51.87
Diarrhea and enteritis (under 2 years)	13.42	22.91
Diarrhea and enteritis (over 2 years)	5.04	6.36
Nephritis	87.98	87.68
The puerperal state	10.36	13.08
Congenital malformation, deaths peculiar to early infancy	68.47	72.74
Suicides	13.13	13.59
Railroad accidents	9.56	9.63
Street-car accidents	1.93	2.42
Automobile accidents	22.05	20.63
Homicides	7.81	8.40
All others	265.79	277.97

The Ohio Health News, after pointing to the decreases in the general death rate and in the infant mortality rates, comments as follows:

Marked decreases in numbers of deaths were reported in the following diseases: Typhoid fever, measles, scarlet fever, whooping cough, influenza, tuberculosis (all forms), cancer, diarrhea and enteritis, and causes peculiar to early infancy. Causes of deaths showing increases were: Smallpox, diphtheria, acute anterior poliomyelitis, rabies, diseases of the heart, Bright's disease, and automobile accidents.

Only 40 of the 88 counties did not report deaths from poliomyelitis during the epidemic of last summer and fall. Eight counties reported deaths from smallpox and nine from rabies.

THE PROBLEM OF AUTOMOBILE EXHAUST GAS IN STREETS AND REPAIR SHOPS OF LARGE CITIES

By J. J. Bloomfield, *Assistant Physical Chemist*, and H. S. Isbell, *Assistant Chemist, Office of Industrial Hygiene and Sanitation, United States Public Health Service*

Nature of Problem

That automobile exhaust gas is highly poisonous has been established beyond question. Perhaps no other toxic substance has received so much attention of late, as indicated by the ever increasing literature on the subject. Scarcely a day passes without mention in the newspapers of a serious accident from automobile exhaust-gas poisoning occurring in garages. It is also well known that among garage workers chronic poisoning, or, perhaps, more correctly, continuous acute poisoning, is common. The seriousness of this hazard in public and private garages and repair shops has been recognized by health authorities throughout the country and is beginning to receive the serious consideration it justly deserves.

Due to the increasing number of automobiles, the problem of the pollution of the air of city streets has come to the fore and many hygienists express deep concern over this problem. Certain types of automobiles of large gasoline consumption, such as trucks and omnibuses, are becoming almost as numerous in the streets of large cities as pleasure cars; and with the new systems of traffic control in vogue in the cities, much starting, stopping, and idling of engines has become necessary. All these factors are conducive to the greater production of exhaust gas, so that at times a haze of blue smoke may actually be seen hanging over the streets of some of our cities. The smoke and its accompanying smell of burnt oil are not, however, an index of the toxicity of exhaust gas. It is generally agreed that the most dangerous substance issuing from the exhaust of an automobile is carbon monoxide, a very subtle poison, in that it is colorless and practically odorless, although usually present in automobile exhaust gas in high concentrations. Carbon monoxide is highly poisonous, because it displaces the oxygen from the hemoglobin molecule, causing asphyxia of the tissues. Most authorities on the physiology of carbon-monoxide poisoning believe that all of the clinical manifestations arising from the breathing of carbon monoxide may be explained on the basis of oxygen privation.

The amount of carbon monoxide produced depends chiefly upon the adjustment of the carburetor, as shown by the investigators of the United States Bureau of Mines (1). In connection with the problems involved in the ventilation of the vehicular tunnel now operating under the Hudson River between New York City and New Jersey, it was necessary to determine the amount and composition of exhaust gas from automobiles. The workers of the

Bureau of Mines undertook this problem and made road tests on 101 automobiles and trucks operated under all sorts of conditions, which showed that the carbon monoxide varied from 0.5 to 14 per cent of the total exhaust gases, averaging about 7 per cent and, under certain conditions, reaching even higher concentrations. This is true when a car is idling. For example, while waiting for the traffic control to change, drivers often use the accelerator several times, presumably to prevent their engines from stalling. This practice yields relatively high amounts of carbon monoxide and smoke.

The air we breathe is a remarkable diluent of the toxic gases that are constantly being emitted from various sources associated with our industrial life. Whether or not there is sufficient air to dilute the vast quantities of toxic automobile exhaust gas at certain congested areas in our large cities where stalled traffic is a common occurrence, is a problem that concerns us at the present time. That the amount of visible smoke and smell emanating from automobile exhausts is at times disagreeable is a fact not to be disputed; but whether or not the amount of exhaust gas in the air of our congested cities is such as to be inherently unhealthful is a question still to be decided.

In order to evaluate the extent of the hazard involved it is essential to determine the amount of carbon-monoxide gas present in the air of the most congested traffic areas of our cities. Such determinations made under traffic and atmospheric conditions should yield a fair index of the amount of toxic gas to which individuals are daily exposed in our streets, and an analysis of such data viewed in the light of our present day knowledge concerning the toxicity of carbon monoxide should go a long way toward answering the question as to whether or not a hazardous condition now prevails in our city streets. It is with such a study of the amount of carbon monoxide present in the atmosphere of our large cities that this paper is mainly concerned. Tests for carbon monoxide in automobile repair shops were also conducted and yielded some interesting results.

Previous Studies

Numerous tests have been conducted in recent years by various investigators in connection with the amount of carbon-monoxide gas existing in the atmosphere of garages and automobile repair shops. One of the most recent and extensive investigations of this sort was the one made by workers of the Bureau of Industrial Hygiene of the New York State Department of Labor (2). However, very few studies have been made concerning the amount of carbon-monoxide gas present in the outside air of our cities. In 1923 Henderson and Haggard (3) reported the conditions in the streets of New York and New Haven as regards atmospheric pollution by automobile exhaust

gas. These investigators made numerous tests under a great variety of atmospheric and traffic conditions. They concluded that a definite hazard existed in the congested areas of our large cities, and they recommended the vertical exhaust pipe discharging above the breathing level as a means of amelioration.

It appeared from this study that traffic patrolmen would be the persons most likely to be affected by exhaust gases in streets; and in 1926 Wilson, Gates, Owen, and Dawson (4) reported blood tests made on traffic patrolmen in Philadelphia. These workers examined the blood of traffic patrolmen after an ordinary eight-hour day's work, and found it to contain from 0 to 30 per cent carbon-monoxide hemoglobin, enough to be associated in some cases with mild subjective symptoms.

The only other study of carbon monoxide in city streets with which we are familiar is that made by workers of the Bureau of Sanitary Engineering of the Department of Health of the city of Chicago (5). In a report issued in 1926 these investigators presented results of tests made of the air in various parts of the city of Chicago. The highest amount of carbon monoxide reported by these workers was 0.36 part per 10,000 parts of air. From this study it was concluded that no hazard from carbon monoxide existed in the streets of Chicago.

Scope of Study

Early in 1927 one of the authors of this paper was engaged in certain work which necessitated visiting some of the large cities in this country, from Boston to San Francisco. It was thought that this trip, embracing all of the largest cities, offered a spendid opportunity to study the amount of carbon monoxide present in the most congested areas of these cities. Such a study would take in variations in traffic control and atmospheric changes which exist in our municipalities, and would yield an excellent index of the extent of atmospheric pollution by automobile exhaust gas.

Since the desideratum of these tests was to study conditions when the hazard was at a maximum, it was decided to include also automobile repair shops for indoor tests. In each city two repair shops, considered as representative of such establishments in the community, were selected for the tests. In addition to obtaining samples of air for the determination of carbon monoxide, a detailed study was made in each place concerning such influencing factors as artificial and natural ventilation, floor space and cubic content of each shop, number of automobiles handled in a day, number of workers exposed, and any other data bearing on this problem. In certain instances the blood of workers was examined in order to determine the degree of carbon-monoxide-hemoglobin saturation.

Likewise, for the street tests, it was desired to study the extreme existing conditions. Hence, with the aid of the police department of each city, two or three of the most congested traffic intersections were selected and tests made at the time when traffic was at a maximum, usually between the hours of 4 and 6 in the afternoon. Most of the street samples were taken at a time when traffic was stalled and cars were idling. These samples were taken as a rule at the breathing level of the pedestrian standing at the curb, and were obtained some 20 or 30 feet from the street intersection, in order to be where idling cars were numerous and also to avoid the open area at the street crossing. Where there was a police officer in the roadway of the intersection, samples were taken beside him in order to determine his exposure to the gas. In connection with the street tests, such factors as the distance between building lines, height of buildings, volume of automobile traffic, wind velocity, temperature, and relative humidity were also recorded. A few tests were made in tunnels used by vehicles and pedestrains, at taxicab stations, and (in one city) inside of auto busses and in offices and residential apartments opening on congested thoroughfares.

All samples were of the so-called "snap" or "grab" instantaneous type, and were taken by breaking the sealed tip of an evacuated 500-cubic-centimeter glass bulb. After obtaining the sample in this manner the broken capillary tip was temporarily sealed with sculptor's clay ("plasticine"), and upon arrival at the laboratory the bulb was sealed in a flame and stored away for subsequent analysis. It was felt that practically no loss of gas was possible in using this technique. Such instantaneous samples taken under congested traffic conditions necessarily yield higher results than would the slower continuous samples taken by other methods; but, since it was desired to study conditions when the exhaust gas in the air was at a maximum, this method of sampling appeared to us to be the most practicable. Our survey commenced in February and continued until late in June of the year 1927, so that all sorts of atmospheric conditions were encountered, thus yielding a fair test of atmospheric pollution by automobile exhaust gas.

Method of Analysis

The iodine pentoxide method was used for the analysis of our samples. This consists essentially in absorbing the other interfering substances in the air sample, oxidizing the carbon monoxide with iodine pentoxide, and determining the amount of iodine liberated. The apparatus used was similar to that of Seidell and Meserve (6), and differs only in the addition of a liquid-air condenser. In 1920

Teague (7), in working out a method for the determination of carbon monoxide in air contaminated with automobile exhaust gas, showed that the only effective means of removing unburned gasoline (which he found to be the only substance vitiating the result of the analysis of carbon monoxide by the iodine-pentoxide method) was in the use of liquid air (−190° C.), which freezes out not only gasoline vapors but also water, carbon dioxide, and probably all of the unsaturated hydrocarbons.

Essentially the method is as follows: Suction is applied at one end of the absorption train in such a manner as to displace (by water) the sample of gas to be analyzed. The carbon monoxide, after passing through the various absorption bulbs and the liquid-air tube, is oxidized by iodine pentoxide at 150° C., and the liberated iodine is absorbed in a solution of potassium iodide. After the absorption train has been swept out by means of carbon-monoxide-free air, the total iodine obtained is titrated with N/500 sodium thiosulphate. The method is rather exacting, but under carefully controlled conditions it yields an accuracy of 0.1 part of carbon monoxide in 10,000 parts of air.

A number of analyses were made of artificial mixtures of air with known amounts of carbon monoxide or gasoline vapor, or both, in order to check the method. The mixtures of carbon monoxide were made by introducing a known amount of carbon monoxide from a gas burette into a known quantity of air. The carbon monoxide was prepared by the action of concentrated sulphuric acid on sodium formate, was purified by bubbling through a barium-hydroxide solution, and was subsequently stored over water. A saturated mixture of gasoline vapor with air was made by shaking 50 cubic centimeters of gasoline in a 2-liter bottle for five minutes. Definite volumes of this were taken with a gas burette after the air-gasoline mixture had stood for half an hour at room temperature. A series of analyses was made in order to test the efficiency and the necessity of using the liquid-air tube to remove unburnt gasoline vapor. Known mixtures of air, gasoline vapor, and carbon monoxide were analyzed, both with and without the liquid-air cooling tube in the train. The results of this series of tests are shown in Table 1.

This experiment demonstrated that it was necessary to remove any gasoline vapor in the determination, and that this removal was accomplished satisfactorily by the use of a liquid-air cooling tube. The determinations of carbon monoxide presented in Table 1 were lower than the theoretical in all cases except in the experiment where the gasoline vapor was not removed by the use of the liquid-air tube. These low results are probably due in part to the fact that the carbon monoxide was not strictly pure. The values which were obtained

on gasoline and carbon-monoxide-air mixtures when liquid air was used are in accord with those obtained in the absence of gasoline vapor.

TABLE 1.—*Showing effect of using the liquid-air condenser tube when determining carbon monoxide in air contaminated with gasoline vapor*

Type of absorption train used	Cubic centimeters of air saturated with gasoline	Cubic centimeters of CO in air mixture calculated	Cubic centimeters of CO found	Difference in per cent
Without liquid air tube	0	1.0	0.95	−5
	0	1.0	.93	−7
	100	1.0	24.30	+2,430
With liquid air tube	0	1.0	.92	−8
	0	1.0	.83	−17
	100	0 0	.00	0
	10	1.0	.91	−9
	10	1.0	.81	−19

CO-free air was used to make the mixtures in all cases.

A series of determinations was also made upon dilute mixtures of carbon monoxide and air. The deviations were less than 3 per cent in mixtures containing 1 to 6 parts CO per 10,000, and less than 10 per cent in those containing about 0.5 part per 10,000.

In all, 250 tests were made for carbon-monoxide gas in the air of streets, repair shops, and auto busses. Of this number, 141 were made in city streets, 102 in repair shops, and 7 in auto busses. In certain instances in which the analysis of a sample showed a relatively small amount of liberated iodine (corresponding to a low CO content), the contents of two or more sample tubes were combined for analysis in order to yield a higher relative degree of accuracy in the subsequent titration. In general, sampling tubes were "pooled" only in those cases in which the samples were obtained at the same location, and where the total amount found was low.

Street Tests

Table 2 summarizes all the tests for carbon monoxide made in the streets of 14 large cities. As has been stated, these tests were usually made at the most congested traffic intersections and at the time of day when traffic was at a maximum. Nearly all samples were taken at the breathing level of a pedestrian and at various points in the street where it may be necessary for a person to walk, such as at the curb near automobiles waiting for the signal to start, in the middle of the road, and near the traffic officer's position. It is felt that these samples represent high average exposures for pedestrians to automobile exhaust gas.

TABLE 2.—*Summary of carbon-monoxide tests made in the streets of 14 cities*

City	Sampling location	Number of tests made	Average CO in parts pe 10,000 of air	Distance in feet between building lines	Average number of stories of buildings affecting air currents	Volume of automobile traffic, cars per hour	Wind velocity in miles per hour	Per cent relative humidity	Remarks

Table 2 presents the number of tests made at each sampling location and the average amount of carbon monoxide, in parts per 10,000 parts of air, found at each sampling spot, the distance between building lines, height of neighboring buildings, the volume of traffic, wind velocity, temperature, and relative humidity. It is to be noted that attempts to find a relation between carbon-monoxide concentration and such factors as wind velocity and traffic volume proved fruitless, though the lowest concentration was found at the point of highest wind velocity, and another low result was obtained in the widest thoroughfare. Possibly a larger body of data might reveal more definite correlations; but, apparently, one or two poorly adjusted carburetors are likely to produce high contamination in spite of the benefits derived from a strong breeze and a clear day.

The average carbon-monoxide concentration at 30 open street locations in 14 cities was found to be 0.65 parts per 10,000. The minimum average amount at any location was 0.2 and the maximum was 1.7 parts per 10,000. A result as high as the maximum for street air was obtained in a vehicular tunnel ventilated by fans, the average amount of carbon monoxide here being 1.7 parts per 10,000. This condition is partly due to the fact that at one of the tunnel exits there is a traffic signal which delays some of the cars for a period as long as 30 seconds; this results in a long line of halted automobiles half the length of the tunnel. This condition could be considerably minimized by providing for freer exit from the tunnel or by controlling the idling of engines in the tunnel during the period when cars are not in motion. At another location we obtained a still higher concentration of carbon monoxide. Our analyses showed that in this location, which is an inclosed tunnellike taxicab stand at a railway station, there existed 2.9 parts of carbon monoxide per 10,000 parts of air. Taxicabs are usually not provided with self-starters, so that once the motors are started it is customary in some instances not to shut them off during the entire working day. This practice obviously increases the amount of carbon-monoxide gas in the air of such places as cab stands at our large railway terminals.

In one city samples were taken in a narrow residential street where cars are continually passing, and on one floor above the sidewalk in an apartment opening on this street, and in an office located on the fourth floor of a building overlooking the congested traffic area The sample taken in the narrow street showed 0.2 parts per 10,000 of carbon monoxide and the sample taken in the room one story above showed 0.4 parts per 10,000. In the office room on the fourth floor of a building located in the business area of the city 0.3 parts per 10,000 of carbon monoxide was found.

Repair Shop Tests

In Table 3 is presented a summary of the tests made in 27 automobile repair shops in 14 cities. In all, 102 determinations were made in these shops. The average amount of carbon monoxide found was 2.1 parts per 10,000 parts of air. Additional data included such information as area of available openings in the room that might serve as a means of natural ventilation, area of ventilating space actually open at the time the tests were conducted, number of automobiles entering and leaving in a day, number of workers exposed, and the presence of artificial ventilation in the workroom.

The data presented in Table 3 show that the highest average amount of carbon-monoxide gas found in any repair shop was 11 parts per 10,000, while the minimum average was only 0.1 part per 10,000. The ratio of available openings to floor space averaged 0.07, and about 43

per cent of the available openings were in use at the time these tests were made. The average number of cars handled was 80 and the average number of persons exposed was 23. Practically all the shops visited depended on natural ventilation to remove the toxic gases produced by automobiles.

TABLE 3.—*Summary of carbon-monoxide tests made in automobile repair shops of 14 cities*

City	Repair shop	Number of tests made	Average CO in parts per 10,000 of air	Ratio of available openings to floor space	Ratio of actual openings to floor space	Number of automobiles handled per day	Number of workers exposed	Principal ventilation	Remarks

Average	2	3.8	2.1	.07	.03	80	23		

All attempts to obtain a correlation between the amount of carbon monoxide and the ventilation factors, such as area of openings, method of ventilation, and number of cars handled, failed to give any decisive results. We are convinced that the idling of a car at the time of sampling produces such a large amount of carbon monoxide as to destroy all the relationships which might be assumed to exist between ventilation and gas content of the garage or repair shop. In fact, from our observations during this study it is felt that no matter what type of ventilation is in use in a repair shop, the carbon-monoxide concentration will be excessive so long as motors are allowed to discharge their exhaust indoors for any considerable

length of time. It is a practice in most shops to test carburetors indoors, a practice that is obviously productive of much exhaust gas. It seems that this gas could be eliminated effectively by relatively simple means. One such simple system was found in use in a repair shop in one of the cities visited. Cars entering the shop were obliged to shut off the motor within 30 seconds after admission. Whenever any carburetor adjusting was to be done, a flexible hose was firmly attached to the exhaust pipe. This hose extended up to the ceiling and was connected to a pipe leading to a ventilator on the roof. With such an arrangement the hot gases pass out through the ventilator.

To test the efficiency of such a system, air samples were taken as follows: An automobile had been placed on the testing block for carburetor test, with its exhaust pipe attached to the flexible hose connection which led to the ventilator in the roof. Three samples taken at the breathing level of the observer immediately after the testing of the engine averaged 0.7 parts of CO in 10,000 parts of air. Five minutes after this test the same automobile engine was allowed to idle without the hose connection to the exhaust pipe, the gases coming out into the shop in a horizontal stream. Samples taken under these conditions averaged 2.0 parts of CO in 10,000 parts of air for periods of engine operation corresponding to those of the first test. This difference in CO content of 1.3 parts per 10,000 is an indication of the efficiency of the simple and inexpensive system of exhaust gas removal described above. It is often argued that such a system would not be practicable in shops where most of the gas comes from cars in motion. This fact may be true in commercial garages and storage places, but was not found to be so in repair shops. In nearly all instances an automobile once brought into the shop remains in one location until repairs have been completed. It is our belief that most of the gas is produced during carburetor testing when the car is not in motion, and at such a time the flexible pipe connection attached to the exhaust should serve to conduct all noxious gases outside the repair room.

In several cities, information was requested by repair-shop proprietors concerning the advisability of the use of an ozone apparatus for eliminating carbon-monoxide gas. Such an apparatus has been investigated by the Bureau of Industrial Hygiene of New York (8), and the conclusion reached by the investigators of that bureau is that ozone does not oxidize carbon-monoxide gas to any appreciable extent. The effects of the ozonator on carbon monoxide were first tested by the New York Bureau of Industrial Hygiene in a gas-tight chamber, and, later, further tests were made in service stations where all determinations showed carbon monoxide to the extent of 3 or 4 parts in 10,000. In an automobile plant visited by us an ozonator was in use in a portion of a large one-story building devoted to

the final assembling and testing of automobiles. As many as 10 machines were tested at one time. An attempt was made to remove some of the exhaust gases by means of local ducts placed within a few inches of the exhaust pipe of each machine and connected with a low-capacity exhaust fan. These ducts were rectangular, about one-third of a square foot in cross-sectional area and removed only about 100 cubic feet of air per minute. The design and location of the exhaust ducts were such as to allow most of the gas to escape into the air of the room. Six tests for carbon-monoxide gas made in the vicinity of the ozonator and test racks showed an average of 2.6 parts per 10,000 parts of air. Blood tests, using the Sayers-Yant pyrotannic acid method (9) were made on five men employed in this room. Three of the men had been working at the test racks for about three hours, and an analysis of their blood taken while at work showed 20, 25, and 20 per cent carbon-monoxide-hemoglobin saturation. A test on the blood of one man working 100 yards away from the test rack showed 15 per cent carbon-monoxide hemoglobin, and the blood of another person employed on final assembly work 50 feet away from the test rack showed 25 per cent carbon-monoxide hemoglobin. This amount of carbon-monoxide hemoglobin is associated with mild subjective symptoms. Possibly the only effect of the use of the ozonator is a psychological one.

Autobus Tests

In two cities, tests were made inside autobusses. Nearly all such conveyances are heated during cold weather by allowing the hot exhaust gases to pass through pipes located on the floor alongside the walls of the car. In case there are leaks in these pipes some exhaust gas will find its way into the bus. The several busses in which tests were made by us showed the presence of exhaust gas by their odor, which in an overheated bus is at times disagreeable. Practically all these busses depend on small openings in the roof or sides of the car for natural ventilation. In seven tests made in six different autobusses, the maximum amount found was 1.0 part of carbon monoxide per 10,000 parts of air, the minimum was 0.1 part, and the average of the seven tests was 0.5 part in 10,000. It was noted that some of the busses at the time these tests were made were overheated, a condition which does not promote comfort and which may increase the symptoms of mild carbon-monoxide poisoning.

Discussion of Results

In Table 4 the results of all our tests for carbon monoxide in streets, repair shops, and autobusses of 14 large cities are summarized in such a manner as to show the percentage distribution of samples according to the concentration of carbon monoxide found. It is apparent that

only 24 per cent of the street samples showed as much as 1 part of carbon monoxide per 10,000 parts of air, whereas 59 per cent of the repair shop samples fall into that group. Of the seven autobus samples only one contained as much as 1 part of carbon monoxide in 10,000 (1.0). Of the 34 street samples (24 per cent of the total street samples) which contained 1 part or more of carbon monoxide in 10,000, 32 (23 per cent of total) had less than 2 parts and 2 (about 1 per cent) contained 2 parts or more of carbon monoxide in 10,000 parts of air. These highest concentrations, however, were obtained in a taxicab station at a railway terminal, and present an unusual condition. It must be noted also, that our street samples tend to represent the worst conditions in streets as regards carbon-monoxide content, since they were obtained in nearly all instances at the most congested traffic centers and at the busiest hours of the day, when the volume of traffic was at its height. The samples were, it should also be noted, of the instantaneous type and taken, as a rule, when traffic was halted and engines were idling, a condition associated with the maximum production of exhaust gas. The autobus samples show a still more favorable result in that practically all of them contained less than 0.01 per cent of carbon monoxide.

On the other hand, the samples taken in the 27 repair shops of the 14 cities show a condition far from favorable. More than half of the samples (59 per cent) contained more than 1 part of carbon monoxide in 10,000, and 18 per cent were over 4 parts in 10,000, an amount considered as decidedly inimical to health. In fact, several determinations in repair shops showed 10 or more parts of carbon monoxide in 10,000. These high results were usually obtained in those repair shops of small floor space, low ceilings, and very small openings to the outdoor air.

TABLE 4.—*Distribution of carbon-monoxide samples obtained in city streets, repair shops, and autobusses*

Carbon monoxide in parts per 10,000	Street samples		Repair shop samples		Autobus samples	
	Number of samples	Per cent of samples	Number of samples	Per cent of samples	Number of samples	Per cent of samples
0.1-0.9	107	76	42	41	6	86
1.0-1.9	32	23	21	21	1	14
2.0-3.9	2	1	20	20	0	0
4.0+	0	0	19	18	0	0
Total	141	100	102	100	7	100

At the present time the accepted criterion concerning the safe limits of carbon-monoxide concentration in air is that advanced by Henderson and his colleagues (10) in 1921 as a result of their work on the physiological effects of automobile exhaust gas for the New York

and New Jersey State Bridge and Tunnel Commission. These workers stated that for the tunnel itself a standard allowing a mix-imum of 4 parts of carbon monoxide in 10,000 of air would be permissible provided the transit through the tunnel would take less than one hour. In summarizing their findings, Doctor Henderson and his collaborators formulated the following general rule: When the time is measured in hours and the concentration of carbon monoxide is expressed in parts per 10,000 parts of air, the physiologic effects may be defined by the equations:

Time × concentration = 3, no perceptible effect.
Time × concentration = 6, a just perceptible effect.
Time × concentration = 9, headache and nausea.
Time × concentration = 15, dangerous.

This work of Henderson's was subsequently confirmed by Sayers, Meriwether, and Yant in 1922 (11). These workers studied the effect of long exposure to low concentrations of carbon monoxide, the effect of strenuous exercise, and the effect of high temperature and humidity in low concentrations. Sayers and his colleagues showed that when a subject exercised strenuously for one hour in an atmosphere containing 2½ parts of carbon monoxide in 10,000 the immediate symptoms of carbon-monoxide poisoning were moderate and the after effects mild to moderate. None of the subjects showed any permanent effects after repeated exposures to carbon monoxide.

From the foregoing discussion of the amount of carbon monoxide that may be tolerated with impunity it is quite obvious that our findings concerning the conditions in the streets of large cities do not reveal a serious condition. Under ordinary circumstances a pedestrian would be exposed to the maximum condition only for a brief period, and even then the concentration of carbon-monoxide gas he would be forced to inhale would be rather low, our findings showing an average carbon-monoxide content of 0.8 part in 10,000 for 141 samples taken when the possible hazard was at a maximum. The same criterion applied to autobus samples shows that there ordinarily exists no hazard due to the contamination of the atmosphere inside such conveyances. It is conceivable, however, that the air of busses may be subject to an even greater range in carbon-monoxide content than that of streets or large garages, since a single badly leaking exhaust pipe discharging continuously into the interior of a bus could produce relatively high concentration. The only person who may be considered on the border-line in connection with outdoor poisoning from automobile exhaust gas is the traffic officer, who is obliged to remain at his post for about eight hours, during two hours of which period the exposure reaches a maximum. That there is a possibility of some grounds for the belief that traffic officers are affected is brought out by Wilson and others (4) who tested the blood of patrolmen after

an eight-hour day's work and found that the maximum carbon-monoxide-hemoglobin content was 30 per cent, a condition associated with mild subjective symptoms. It would be interesting to make a further study into the physiological effects experienced by traffic officers at congested intersections, and, in case the findings warranted action, the time of duty at points of continual congestion might be diminished in order to minimize the hazard.

Applying the same standards to repair shops it is apparent that a real hazard exists in such establishments, as revealed by the results of 102 samples obtained in our study. Only 41 per cent of these samples showed a carbon-monoxide content less than 1 part in 10,000. Workers of the United States Buréau of Mines (13) recently reported carbon-monoxide tests made with a recording instrument in two garages. This carbon-monoxide recorder showed that the average concentration in any one day in one garage never exceeded 1 part per 10,000 and the maximum average in another garage for one day reached 1.6 parts per 10,000. However, at times the carbon-monoxide content in these garages exceeded 8.9 parts per 10,000, and the maximum average for any one hour was found to be 4.3 parts per 10,000. Had these tests been made during cold weather, no doubt the carbon monoxide would have reached higher concentrations. Similar conditions were found by the workers of the Bureau of Industrial Hygiene of New York in some of their tests in garages and repair shops (2), (12). Although the average conditions found by these workers did not show as high an amount of carbon monoxide in the atmosphere of the repair shops visited by them as that obtained in the present investigation, yet as a result of their research the investigators of the New York Bureau of Industrial Hygiene concluded that the only safe method is ventilation, and that the carbon monoxide should not exceed 0.5 part in 10,000 volumes of air. In connection with regulations governing ventilation of public garages the municipal code (section 2196) of the city of Chicago requires that the carbon-monoxide content should not exceed 2 parts per 10,000 parts of air.

The average of 102 determinations of the carbon monoxide in the atmosphere of 27 repair shops investigated in the present survey showed 2.1 parts of this gas in 10,000 volumes of air. The possibility of such an amount of carbon monoxide being inhaled by an active worker over a period of eight hours reveals a serious condition in automobile repair shops. Our experience has been that even with a well-designed system of ventilation in use the atmosphere of a repair shop will show as much as 0.6 part of carbon monoxide in 10,000 parts of air. It is our belief that no automobile motor should be permitted to run longer than 30 seconds in any inclosed garage except when being driven in or out of the garage. Testing of car-

buretors and any other operation of an engine indoors should be done only when some means has been taken to remove the exhaust gas directly to the outer atmosphere, possibly by means of a flexible hose connection to the exhaust pipe, as described earlier in this paper.

Summary

This survey was undertaken to ascertain whether or not a health hazard from carbon monoxide existed in the streets of our large cities, inside of autobusses, and in repair shops. Fourteen of the largest cities in the country were visited, having a combined population of over 19,000,000, and 250 samples of air were obtained for carbon-monoxide analysis. These samples were analyzed by the iodine-pentoxide method, using a liquid-air cooling tube which was shown to be necessary in order to eliminate gasoline vapor, a substance which tends to vitiate the results of the analysis. Our street samples were taken in such a manner as to approach the most congested conditions that may exist at a busy traffic intersection. Hence, it is felt that these results indicate the maximum hazard from automobile exhaust gas that may exist to-day in our metropolitan thoroughfares. The average of 141 tests made in city streets at peak hours of traffic showed a contamination of 0.8 part of carbon monoxide per 10,000 parts of air. Only 24 per cent of all the street samples had more than 1 part of carbon monoxide in 10,000 of air, and in only one location, a covered passageway, was there as much as 2 parts per 10,000. Samples taken inside of autobusses yielded even lower concentrations of carbon-monoxide gas. The figures for street air, when viewed in the light of present day standards of exposure to carbon monoxide, do not reveal the existence of a health hazard from this source in our city streets. The only individual who may possibly be exposed to a health hazard from inhaling street air containing automobile exhaust gas is the traffic officer. This potential hazard may be minimized by diminishing the duration of exposure at the most congested traffic stations.

Of the 102 tests made in 27 garages in the 14 cities visited, the average carbon-monoxide content was found to be 2.1 parts in 10,000. More than half of the samples (59 per cent) contained over 1 part of carbon monoxide, and 18 per cent of all the samples contained over 4 parts of this gas in 10,000 parts of air. These results for repair shops show a dangerous condition that demands the serious consideration of those concerned. This hazard in repair shops may be reduced to a minimum by not allowing the motors of automobiles to run longer than 30 seconds unless the car is in necessary motion or the exhaust is connected to the outside air by a direct air-tight outlet

of ample caliber. Without such outlet no automobile engine should be allowed to run indoors, except to reach its berth or to leave by the shortest route. All of these samples were taken in garages of considerable size. The great danger to life is unquestionably in the small private garage containing one or two cars. Under any circumstances the discharge of an automobile exhaust into a roofed inclosure should be regarded as a hazardous act.

Acknowledgments.—The writers desire to express their appreciation to Surg. J. P. Leake and to Surg. L. R. Thompson for guidance in the conduct of this study, and to Dr. E. Elvove for supervision of the chemical tests.

COURT DECISIONS RELATING TO PUBLIC HEALTH

Nuisance from overflow of town septic tank enjoined.—(Oklahoma Supreme Court; Town of Jennings *v.* Pappenfuss, 263 P. 456; decided January 24, 1928.) An action was brought to enjoin a town from maintaining a nuisance and to compel it to abate the same. The plaintiff alleged that the overflow upon her land from a septic tank of the town sewer constituted a nuisance, the odor and stench being of such extent that it was practically impossible to live upon her farm. The trial court found that the town had been maintaining a nuisance by permitting the overflow from the septic tank to flow into a ditch and over and upon the plaintiff's land, and adjudged that a permanent injunction be granted the plaintiff, enjoining the defendant from maintaining the nuisance, and that defendant proceed at once to abate the nuisance. On appeal the judgment of the lower court was affirmed by the supreme court.

Revocation of license for manufacture and bottling of soft drinks upheld.—(Maine Supreme Judicial Court; Appeal of Bornstein, 140 A. 194; decided January 26, 1928.) Chapter 155, Laws of 1925, provided for the licensing, by the commissioner of agriculture, of any person, firm, or corporation manufacturing or bottling for sale at wholesale any drink product or other nonalcoholic beverage within the State, and also empowered the commissioner to revoke or suspend any license whenever any provisions of the act had been violated. The act also provided that "Whenever artificial colors or flavors are used in the manufacture of drink products or other nonalcoholic beverages, the bottle or other container shall be distinctly labeled or crowned 'Artificially colored and flavored.'" The appellant had been licensed under the act and, after notice and hearing, the commissioner revoked such license on the ground that the appellant had bottled a beverage, containing artificial color, in bottles or containers not labeled or crowned "Artificially colored and flavored." On appeal before the supreme court it was urged that there was a violation of the appellant's constitutional guaranties in that he was deprived of a property right without due process of law, but the court in upholding the revocation said:

> The constitutional questions argued are not open to the appellant in this proceeding. The single issue here is revocation of the license granted by the commissioner. In accepting the license and acting under it, the appellant consented to all conditions imposed thereby. He took it subject to such conditions as the legislature had seen fit to impose. Such license is in no sense a contract or property, immunity, or privilege. State *v.* Cote, 122 Me. 450, 120 A. 538; Burgess *v.* Brockton, 235 Mass., 95, 126 N. E. 456; Com. *v.* Kinsley, 133 Mass. 578; 17 R. C. L. 554. The requirements of the act as to labeling or crowning bottles and containers must be read into the license as a condition to which the appellant consented. State *v.* Cote, supra. If the validity of the act in its branding requirements is to be tested, it must be in another and different proceeding.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Garbage Disposal at Highlands, N. J. Anon. *The American City*, vol. 38, No. 1, January, 1928, pp. 147–148. (Abstract by C. R. Cox.)

The population of Highlands varies from 2,000 in winter to about 10,000 in summer. A United States standard incinerator was installed in June, 1927, with a guaranteed capacity per 24 hours of 24 tons of refuse consisting of 65 per cent garbage, with moisture content less than 70 per cent, and 35 per cent rubbish without added fuel. Tests indicated the capacity to be 72 tons per 24 hours and that the temperature in the combustion chamber was 2,000° F. Three charging openings are used, one for rubbish onto the firing hearth, one for wet garbage onto the drying grates, and one for the carcasses of animals, which are placed in the bottom of the combustion chamber. Collections from August 1 to September 10 amounted to 503 tons of refuse, which was incinerated at the following costs: Labor, $318.35; wood, $30; coal, $42; electric power, $14, or a total of $404.35, or $0.803 per ton. The cost of collection was as follows: Labor, $891, and gas and oil, $86.40, or an average of $1.90 per ton. About $270 was saved during the 36-day period over former cost of disposal on a sanitary dump where lime and earth cover was used to prevent odors.

A New Diluent for Paris Green. P. A. Dalal and E. E. Madon. *Indian Medical Gazette*, vol. 62, No. 10, October, 1927, pp. 554–555. (Abstract by W. A. Hardenberg.)

One of the problems in anopheline control in Bombay has been "sprinkler tanks," which are elevated tanks provided for automatic gravity fire service. These tanks mostly contain clean water, are generally 30 to 60 feet in width and length and 6 feet deep, and even when covered are not mosquito-proof. There are also other cisterns, usually containing clean water, which are used for a variety of purposes. Pyrethrum-base powders were not effective. No satisfactory diluent for Paris green was available. Cork powder is effective but too expensive; sawdust sinks after a short time; fine road dust sinks too quickly and does not withstand agitation or wind action; flue dust from boiler flues was quite satisfactory; but French chalk, which is finely powdered magnesium silicate, proved best. This is readily obtainable in India in smooth hard pieces, which can be ground in a mortar. To treat a tank 32 by 16 by 6 feet deep, 40 grains of Paris green and 8 ounces of French chalk were used. Though a strong wind was blowing, a satisfactory film was maintained and the treatment proved effective. This mixture is considered ideal for use on small cisterns.

Malaria and Malaria Control in Turkey (Malaria und Malariabekampfung in der Tuerkei). E. Martini. Leaflet of 2 pages, Hamburg, Germany. (Abstract by A. L. Dopmeyer.)

Malaria is a disease of very great importance in Turkey. Although there is very little malaria in Constantinople, there is a great deal of it in the district of Anatolia. All sections, however, are said to suffer heavily from the disease, and in the warm lowlands of the west and south the severe forms of the disease are found.

The climate of the country is variable. The elevated plateaus are dry, cold in winter and very warm in summer. The northern part has a damp, cold climate and the south has extremely warm summers and mild winters. In contrast to the usual three species of *Anopheles* mosquitoes found in Europe north of the Alps, there are eight distinct species here. In the mountainous sections the *Anopheles superpictus* is abundant, and in other sections where water is plentiful, the streams serve as breeding places for *Anopheles elutus* and *maculipennis*.

In 1925 the new government took an active interest in malaria control and formed so-called malaria missions consisting of a chief medical officer and subordi-

nate medical and other personnel. Malaria stations were established for the treatment of cases in order to check the spread of infection. The first mission was started in Angora and later ones were established at other points; and it is significant to note that, according to statistics compiled, the malaria reduction depends in large degree on the length of time the mission has been operating.

The success of the work at Angora is evidenced by the fact that a few years ago it was thought that it might be necessary to move the capital from that city on account of malaria, whereas the disease in that city to-day is practically non-existent.

The total cost of malaria control work in Angora for 1926, with a population of 30,000, was $35,700 or $1.19 per capita.

Report of an Investigation of a Malaria Epidemic in Solo, 1926. S. L. Brug and Dr. E. W. Walch. *Mededeelingen Dienst d. Volksgezondheid in Nederlandsch-Indie,* Foreign Edition, 1927. Part 3, pp. 531–579. (Abstract by H. R. Crohurst.)

This article contains a description of conditions in Solo, the third largest town of the Netherland Indies, during the malarial epidemic of 1926. There are presented data covering the hydrographic conditions of the town, history of malaria at Solo, area involved, and the center of the 1926 epidemic, progress of the epidemic, the examination of *Anopheles,* the distribution of quinine, the probable cause of the epidemic, and future control measures.

On the evidence of indirect data it was supposed that the vectors of the epidemic came chiefly from the bed of a storm-water canal, which in the dry season shows numerous isolated pools. Owing to the rains setting in so late in 1925 this canal had not been flushed during an abnormally long time. With this opinion corresponded the fact that the heaviest affected native villages lay precisely where the bed of the canal showed the greatest number of pools.

The direct proof regarding the storm-water canal could not be given, as it was only once dry during a sufficient number of days during the investigation to be examined for the presence of larvæ. At that time it contained almost exclusively larvæ of *M. vaga,* which does not exclude the fact that before this time other species may have bred there.

Only one *Anopheles* was found infected, namely, an *M. rossi.* The larvæ of this species were found only in the northern part of the town, but there, in small numbers, and in breeding places of a very different nature. Other potential carriers found during the investigation were somewhat larger numbers of *M. aconita* and *N. fuliginosus.*

The Government distributed without charge, during the epidemic, 420,000 tabloids of 0.2 gram of bisulphate of quinine. Prophylaxis was applied especially in the schools.

It is recommended that the condition of the storm-water canal be observed in the future, as it is believed that the river Pepe carries too little water in the dry season to effect a proper flushing of the canal precisely at the time that it is most necessary.

Report of Some Experiments on the Efficiency as Insecticides of "Flit," "Rids," and Some Other Preparations Made at the Medical Laboratory at Weltevreden. S. L. Brug and Dr. J. Van Slooten. *Mededeelingen Dienst d. Volksgezondheid in Nederlandsch-Indie,* Foreign Edition, 1927. Part 3, pp. 524–530. (Abstract by H. R. Crohurst.)

The authors describe the effects on mosquitoes, flies, cockroaches, and bedbugs, by spraying with various insecticides, "flit," commercial "rids," and "rids" prepared in the laboratory with kerosene, carbon tetrachloride, methyl salicylate, and various mixtures of each.

The authors conclude: "Flit kills such insects as flies and mosquitoes very readily. With commercial 'Rids,' and with 'Rids' prepared in the medical

laboratory nearly the same results were obtained. Pure kerosene is certainly considered somewhat inferior to these. There is no objection to omitting the methyl salicylate from the 'Rids' formula, the addition of a quantity of carbon tetrachloride of 2 parts to 100 parts of kerosene being sufficient to guarantee a good effect. One gets thereby a simpler and cheaper preparation with the same effects. On account of its irritating effects on the skin, conjuctiva, and nasal mucosa, and on account of producing stains, 'Flit' is less recommendable. Unless one can spray the insects repeatedly, the effect on cockroaches is doubtful. Since the penetrating power of an insecticide fluid applied by means of a spray is not sufficient to reach bedbugs in all their hiding places, all these preparations are of little importance in the destruction of such vermin."

Italy's Campaign Against Malaria. Arturo Castiglioni. *British Medical Journal*, No. 3475, August 13, 1927, pp. 278–289. (Abstract by R. E. Tarbett.)

From ancient times malaria has been a grave problem in the area now comprising the Kingdom of Italy. Archaeologists have shown that the Etruscans attempted to drain the swamps and marsh land and later the Romans actually eradicated these areas in the Campagna Romana. After the fall of the Roman Empire this area again became malarious.

Grassi, Celli, Marchiafara, and Bignami collaborated with Ross in the study of the malaria parasite and mode of transmission of malaria. They also inaugurated the legislation on the supply of quinine to the malarious regions. Quinine is prepared by the State laboratories and sold to certain public retailers. All profits are placed in a special fund for carrying on malaria control work. Malaria is classified as an occupational disease and carries the right to indemnity.

The usual methods employed in malaria control are carried on. The author places considerable stress on the raising of cattle in the malarious regions and the development of nonhuman-stinging *Anopheles*.

From 1887–1902 there was an average of 15,000 deaths per annum; 1903–5, 8,000 deaths per annum; and a decline to 2,000 in 1914. An increase reaching 11,487 in 1918 occurred during the war period. Since that time a rapid decrease has occurred, the deaths in 1923 being 3,000.

The Water Supply Project of the Mahoning Valley Sanitary District. W. H. Dittoe. *Journal American Water Works Association*, vol. 18, No. 6, December, 1927, pp. 655–663. (Abstract by M. F. Trice.)

"The purpose of this paper is to explain briefly the conditions leading to the establishment of the sanitary district, the provisions of the sanitary district act controlling the procedures followed, and the general features of the recommended plan." The Mahoning River, draining an area of approximately 1,000 square miles, is grossly polluted by sewage and industrial wastes, and yet serves as a source of public water supply for Warren, Niles, and Youngstown, the three principal cities of the valley, each of which operates a filtration plant. In spite of resourceful control these plants deliver to consumers a highly unsatisfactory water. Upon action by the city councils of Niles and Youngstown, and application to the court of common pleas of Mahoning County, which, after due hearing of the court on February 2, 1926, "ordered the formation of a district for the purpose of providing a satisfactory public water supply for the two municipalities."

Provisions of law.—The sanitary district act of Ohio permits two or more political subdivisions to organize for the following purposes: (*a*) Improved water supply, and (*b*) improved sewage disposal. This district was organized solely for improving the water supply, and therefore sewage disposal is not discussed. The court appoints a board of directors which supervises the work. The Ohio law requires the board to prepare plans for the improvements. The board allows hear-

ings relative to the plans, estimates costs, assesses the political units benefited proportionately, issues bonds for the execution of the plan, is empowered to proceed with construction either directly or by contract, and after completion of the project supervises maintenance and operation.

The plan for the district water supply.—The essential features of the plan include (1) the Meander Creek Reservoir, formed by the construction of the Mineral Ridge Dam; (2) purification and pumping works located immediately below dam; (3) pipe lines for delivery of the purified supply to the two cities; (4) a covered distributing reservoir in Youngstown and a steel standpipe in Niles, for reserve storage of water on the distributing systems.

The cost of execution of this plan is estimated at $9,150,000, made up of the following principal elements:

Dam and reservoir	$3, 781, 960
Purification and pumping works	2, 310, 030
Pipe lines and distributing reservoir for Youngstown	2, 661, 600
Pipe lines and standpipe for Niles	396, 410

The principal features of the above elements are discussed broadly, as, for instance, the dimensions and size of the dam, capacity and yield of the reservoir and the opportunity for future increase of the supply, the highway changes and resulting bridge construction involved, the design and provisions of the purification plant (number of units, their dimensions and capacity), pumping equipment (steam-turbine-driven), delivery mains from purification plant to above cities, and the improvements to be made at these municipalities. Advantages of district procedure are also discussed.

Recent Advances in Controlling Chloro-Tastes and Algæ Development. L. H. Enslow. *Journal American Water Works Association*, vol. 18, No. 5, November, 1927, pp. 621–640. (Abstract by C. R. Cox.)

. This paper reviews the experiences of various plants on this continent where taste problems, due to the chlorination of water, existed. Superchlorination at one plant in Dallas, Tex., followed by subsequent chlorination of the filtered effluent, was effective in destroying tastes due to vegetable matter and algæ in the raw lake water when the dose was sufficient to produce a residual of 0.3 p. p. m. or more. Experience at the Turtle Creek plant at Dallas, where iron sulphate and lime are employed to coagulate and soften the supply, indicated that the filtered water delivered to the consumer had a noticeable chlorine taste, although that in the open clear-water basin did not. It was found that these tastes were due to formation of stable hypochlorites by the reaction of chlorine and the alkaline salts in the water. This action was prevented by lowering the pH value of the filtered water prior to chlorination. The destruction of chloro-phenol tastes by the practice of superchlorination and dechlorination at Toronto, Canada, is reviewed. Importance of having sufficient reaction time between the application of the chlorine dose and the addition of the dechlorinating agent was emphasized. The prevention of formation of chloro-phenol tastes by the addition of ammonia before chlorine is then reviewed and special mention is made of satisfactory results secured at Greeneville, Tenn. where 0.25 p. p. m. ammonia were added to the raw water previous to the addition of chlorine to the water passing through the mixing basin. The cost of this treatment was about 60 cents per million gallons of water treatment. Ammonia solutions are made by the addition of 6.25 pounds of ammonia gas to 100 gallons of water, which solution was fed through an ordinary orifice box. It is significant to note that ammonia prevents the formation of chloro-phenol tastes, but does not destroy such tastes once they are formed, so that the ammonia has to be added prior to the chlorine. The suppression of algal growth in outdoor swimming pools and coagulation basins in the South by the use of chlorine is

briefly reviewed. The discussion of this paper reviewed the method of treating phenolic waste at a coke plant in Troy, N. Y., and in the destruction of chlorophenol tastes at a filtration plant in Rochester, N. Y., by the use of permanganate of potash. The doses of permanganate varied from 1.0 to 1.6 pounds per million gallons of water treated. It was also pointed out in the discussion that organic growths on sand grains can be effectively prevented by moderate doses of chlorine applied to the raw water or to the wash water. The advantages of prechlorination in the treatment of grossly polluted waters were emphasized.

Small Iron Removal Plant for Red Bank Water Works. Wellington Donaldson. *Engineering News-Record*, vol. 100, No. 3, January 19, 1928, pp. 112-114. (Abstract by W. M. Olson.)

This article gives the history, design considerations, and operating data concerning the new 1.5 m. g. d. plant for treating the ground water supply of Red Bank, N. J. Three photographs and an excellent cross section make clear the essential features of the plant designed to eliminate objectionable staining properties of the raw water. Raw water is pumped to a simple cascade-type aerator, flows downward through three pressure filters, and thence up to the wash-water tank, from which it spills over a weir into the distributing reservoir. Standard horizontal pressure filters were adopted in order to have the plant operate as nearly automatically as possible. Results of tests are included to show the superiority of sand to coarse contact filters.

Excessive algal growths developing in the reservoir after the installation of the new plant were combated successfully by chlorinating the effluent. The operation of the plant requires the attention of one man for less than an hour each day. The treatment works, costing $52,881, are a good example of careful design to fit local conditions.

DEATHS DURING WEEK ENDED MARCH 17, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended March 17, 1928, and corresponding week of 1927. (From the Weekly Health Index, March 21, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended Mar. 17, 1928	Corresponding week, 1927
Policies in force	70, 602, 861	67, 030, 693

[1] Annual rate per 1,000 population.
[2] Deaths under 1 year per 1,000 births. Cities left blank are not in the registration area for births.
[3] Data for 66 cities.
[4] Deaths for week ended Friday, Mar. 16, 1928.
[5] In the cities for which deaths are shown by color, the colored population in 1920 constituted the following percentages of the total population: Atlanta, 31; Baltimore, 15; Birmingham, 39; Dallas, 15; Fort Worth, 14; Houston, 25; Indianapolis, 11; Kansas City, Kans., 14; Knoxville, 15, Memphis, 38; Nashville, 30; New Orleans, 26; Richmond, 32; and Washington, D. C., 25.

PREVALENCE OF DISEASE

No health department, State or local, can effectively prevent or control disease without knowledge of when, where, and under what conditions cases are occurring

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 97 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of nearly 31,196,000. The estimated population of the 92 cities reporting deaths is more than 30,580,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended March 10, 1928, and March 12, 1927

	1928	1927	Estimated expectancy
Cases reported			
Diphtheria:			
42 States	1,707	1,719	
97 cities	1,034	1,083	923
Measles:			
41 States	17,401	15,788	
97 cities	6,754	5,540	
Poliomyelitis:			
42 States	31	12	
Scarlet fever:			
42 States	5,102	6,277	
97 cities	1,800	2,644	1,158
Smallpox:			
42 States	1,241	945	
97 cities	135	174	134
Typhoid fever:			
42 States	122	227	
97 cities	22	45	39
Deaths reported			
Influenza and pneumonia:			
92 cities	1,249	1,252	
Smallpox:			
92 cities	0	0	

City reports for week ended March 10, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine years. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics, or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years.

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria		Influenza		Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
			Cases, estimated expectancy	Cases reported	Cases reported	Deaths reported

The following table gives the rates per 100,000 population for 101 cities for the five-week period ended March 10, 1928, compared with those for a like period ended March 12, 1927. The population figures used in computing the rates are approximate estimates as of July 1, 1927 and 1928, respectively, authoritative figures for many of the cities not being available. The 101 cities reporting cases had estimated aggregate populations of approximately 31,050,000 in 1927

and 31,657,000 in 1928. The 95 cities reporting deaths had nearly 30,370,000 estimated population in 1927 and nearly 30,961,000 in 1928. The number of cities included in each group and the estimated aggregate populations are shown in a separate table below:

Summary of weekly reports from cities, February 5 to March 10, 1928—Annual rates per 100,000 population compared with rates for the corresponding period of 1927 [1]

FOREIGN AND INSULAR

THE FAR EAST

Report for the week ended February 25, 1928.—The following report for the week ended February 25, 1928, was transmitted by the eastern bureau of the health section of the secretariat of the League of Nations, located at Singapore, to the headquarters at Geneva:

Plague, cholera, or smallpox was reported present in the following ports:

PLAGUE

Egypt.—Suez.
Aden Protectorate.—Aden.
India.—Bassein, Bombay, Rangoon.
Ceylon.—Colombo.
Straits Settlements.—Singapore.
Dutch East Indies.—Makassar.

CHOLERA

India.—Bassein, Calcutta, Madras, Negapatam, Rangoon.
Siam.—Bangkok.
French Indo-China.—Saigon.

SMALLPOX

Egypt.—Alexandria.
Ceylon.—Colombo.
India.—Bombay, Calcutta, Cochin, Madras, Moulmein, Rangoon, Vizagapatam.
French India.—Pondicherry.
French Indo-China.—Saigon.
Dutch East Indies.—Belawan-Deli, Pontianak.
China.—Shanghai, Hong Kong.

Returns for the week ended February 25 were not received from the following ports:

Dutch East Indies.—Banjermassin, Samarinda.
Kuantung.—Port Arthur, Dairen, towns of the South Manchurian Railway zone.
Union of Socialist Soviet Republics.—Vladivostok.

ARABIA

Aden—Plague—January 9–February 22, 1928.—A total of 303 cases of plague with 188 deaths has been reported at Aden for the period January 9 to February 22, 1928.

BELGIAN CONGO

Matadi—Yellow fever—January 26–February 19, 1928.—During the period January 26 to February 6, 1928, 8 cases of yellow fever with 6 deaths were reported at Matadi, Belgian Congo. Of these, three cases with two deaths were in Europeans.

A suspect case of yellow fever was reported at the quarantine station of Ango Ango, below Matadi, February 9, 1928. The patient died February 10.

Quarantine was lifted at Matadi on February 19, 1928.

CANADA

Provinces—Communicable diseases—Week ended March 10, 1928.—The Canadian Ministry of Health reports cases of certain communicable diseases from seven Provinces of Canada for the week ended March 10, 1928, as follows:

Disease	Nova Scotia	New Brunswick	Quebec	Ontario	Manitoba	Saskatchewan	Alberta	Total
Cerebrospinal fever				1				1
Influenza	12			13		3		28
Smallpox				20		7	7	34
Typhoid fever		2	7	8			1	18

Quebec Province—Communicable diseases—Week ended March 10, 1928.—The Bureau of Health of the Province of Quebec reports cases of certain communicable diseases for the week ended March 10, 1928, as follows:

Disease	Cases	Disease	Cases
Chicken pox	50	Scarlet fever	80
Diphtheria	53	Smallpox	18
German measles	21	Tuberculosis	59
Influenza	4	Typhoid fever	7
Measles	293	Whooping cough	29

CUBA

Santiago de Cuba—Malaria—March 17, 1928.—Under date of March 17, 1928, 136 cases of malaria were reported at Santiago de Cuba.

CZECHOSLOVAKIA

Communicable diseases—January, 1928.—During the month of January, 1928, communicable diseases were reported in Czechoslovakia as follows:

Disease	Cases	Deaths	Disease	Cases	Deaths
Anthrax	4		Paratyphoid fever	6	1
Cerebrospinal meningitis	25	3	Puerperal fever	55	21
Diphtheria	937	71	Scarlet fever	1,372	36
Dysentery	10		Trachoma	226	
Malaria	1		Typhoid fever	455	34

EGYPT

Suez—Plague—February 19-March 1, 1928.—During the week ended February 25, 1928, four cases of plague were reported at Suez, Egypt. On March 1, 1928, a fatal septicemic case was reported.

From January 1 to February 25, 1928, 17 cases of plague were reported at Suez, as compared with 13 cases during the corresponding period of 1927.

ESTONIA

Communicable diseases—January, 1928.—During the month of January, 1928, communicable diseases were reported in the Republic of Estonia as follows:

Disease	Cases	Disease	Cases
Cerebrospinal meningitis	7	Scarlet fever	402
Diphtheria	48	Tuberculosis	181
Measles	50	Typhoid fever	49

Population, estimated, 1,114,630.

GREAT BRITAIN

Leeds, England—Smallpox.—Under date of March 5, 1928, two outbreaks of smallpox were reported in the Leeds consular district, with 11 cases. Both outbreaks were stated to be mild. The first outbreak occurred in the small mining village of Swillington, with 8 cases. At Leeds, three cases were reported March 1, 1928.

JAPAN

Influenza—January 1-February 10, 1928.—The Home Office of Japan, at Tokyo, has published a statement that there were 27,411 cases of influenza with 395 deaths in Japan from January 1 to February 10, 1928. On March 17, 1928, conditions were said to have greatly improved.

PERU

Arequipa—Mortality from communicable diseases—December, 1927—January, 1928.—Mortality from communicable diseases was reported at Arequipa, Peru, during the months of December, 1927, and January, 1928, as follows:

Disease	Deaths		Disease	Deaths	
	December, 1927	January, 1928		December, 1927	January, 1928
Gastroenteritis	15	11	Scarlet fever	1	
Influenza		2	Tuberculosis	11	28
Measles		1	Typhus fever	1	2

Population: 44,300 in January, 1928.

General mortality.—The total number of deaths from all causes reported at Arequipa for the months of December, 1927, and January, 1928, was 61 and 92, respectively.

Prevailing diseases.—Diseases prevalent at Arequipa were stated to be bronchitis, pneumonia and broncho-pneumonia, enteritis and gastroenteritis in children; a few cases of smallpox, tuberculosis, typhoid fever, and typhus fever.

SENEGAL

Plague—January, 1928.—During the month of January, 1928, five cases of plague were reported in Senegal, occurring in the interior.

SYRIA

Beirut—Smallpox outbreak—January-February, 1928.—Under date of February 23, 1928, an outbreak of epidemic smallpox was reported at Beirut, Syria, with 46 cases reported from January 26 to February 19, 1928.

URUGUAY

Montevideo—Communicable diseases—November, 1927.—During the month of November, 1927, communicable diseases were reported at Montevideo, Uruguay, as follows:

Disease	Cases	Deaths	Disease	Cases	Deaths
Diphtheria	28	3	Tuberculosis	145	95
Measles	59	6	Typhoid fever	4	3
Scarlet fever	14				

Population, estimated, 439,129.

VENEZUELA

Tacata and Cua, State of Miranda—Plague—March 11, 1928.—Under date of March 14, 1928, plague was reported at Tacata and Cua, in the State of Miranda, Venezuela, about 100 kilometers from Caracas, near the State of Aragua. The last case was said to have been reported March 11. Precautions against the spread of the disease were taken.

VIRGIN ISLANDS

Communicable diseases—February, 1928.—During the month of February, 1928, communicable diseases were reported in the Virgin Islands of the United States as follows:

Island and disease	Cases	Remarks
St. Thomas and St. John:		
Chancroid	2	
Gonorrhea	3	
Leprosy	2	Secondary, 2.
Pellagra	1	
Syphilis	3	Secondary, 2.
Whooping cough	1	
St. Croix:		
Syphilis	3	Secondary.
Uncinariasis	7	Necator americanus.

CHOLERA, PLAGUE, SMALLPOX, TYPHUS FEVER, AND YELLOW FEVER

From medical officers of the Public Health Service, American consuls, health section of the League of Nations, and other sources. The reports contained in the following tables must not be considered as complete or final as regards either the list of countries included or the figures for the particular countries for which reports are given.

UNITED STATES PUBLIC HEALTH SERVICE

HUGH S. CUMMING, *Surgeon General*

DIVISION OF SANITARY REPORTS AND STATISTICS

Asst Surg. Gen R. C. WILLIAMS, *Chief of Division*

The PUBLIC HEALTH REPORTS are issued weekly by the United States Public Health Service through its Division of Sanitary Reports and Statistics, pursuant to acts of Congress approved February 15, 1893, and August 14, 1912.

They contain: (1) Current information of the prevalence and geographic distribution of preventable diseases in the United States in so far as data are obtainable, and of cholera, plague, smallpox, typhus fever, yellow fever, and other communicable diseases throughout the world. (2) Articles relating to the cause, prevention, or control of disease. (3) Other pertinent information regarding sanitation and the conservation of the public health.

The PUBLIC HEALTH REPORTS are intended primarily for distribution to health officers, members of boards or departments of health, and those directly or indirectly engaged in or connected with public health or sanitary work. Articles of general or special interest are issued as reprints from the PUBLIC HEALTH REPORTS or as supplements, and in these forms are available for general distribution to those desiring them.

Requests for and communications regarding the PUBLIC HEALTH REPORTS, reprints, or supplements should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

The Public Health Service is unable to supply the demand for bound copies of the PUBLIC HEALTH REPORTS. Librarians and others receiving the PUBLIC HEALTH REPORTS regularly should preserve them for binding, as it is not practicable to furnish bound copies on individual requests.

ADDITIONAL COPIES
OF THIS PUBLICATION MAY BE PROCURED FROM
THE SUPERINTENDENT OF DOCUMENTS
U.S GOVERNMENT PRINTING OFFICE
WASHINGTON, D. C.

VOL. 43 APRIL 6, 1928 NO. 14

MENINGOCOCCUS MENINGITIS IN THE UNITED STATES, 1928

During the first 12 weeks of 1928, more cases of meningococcus meningitis were reported in the United States than were reported during the corresponding period of 1926 or 1927. However, the total number of cases is small in proportion to the population, and some of the increase may be accounted for by better reporting, resulting in the recording of a larger percentage of the cases which occurred in 1928 than was recorded for the other years.

The figures for 42 States, having a population of about 105,000,000, are as follows:

Cases of meningococcus meningitis reported by 42 States, January 1 to March 24, 1928, inclusive, and corresponding periods of 1926 and 1927

	Cases
1926	562
1927	698
1928	1, 179

The highest prevalence is reported from the Mountain States and the lowest case rates are in the South Atlantic States.

The following table shows the distribution of the cases and the case rates in different sections of the country.

Cases of meningococcus meningitis reported during the first 12 weeks of 1928, with annual rates per 100,000 population, by geographical divisions

	Number of cases	Rate per 100,000
New England (5 States)	40	2. 23
Middle Atlantic (3 States)	229	3. 96
East North Central (4 States)	203	4. 88
West North Central (7 States)	153	5. 03
South Atlantic (6 States and District of Columbia)	35	1. 30
East South Central (3 States)	35	2. 22
West South Central (4 States)	59	2. 18
Mountain (7 States)	282	32. 06
Pacific (3 States)	143	8. 84
Total (42 States and District of Columbia)	1, 179	4. 86

ALCOHOLISM AND DRUG ADDICTION AS SEEN IN UNITED STATES MARINE HOSPITALS

By H. McG. Robertson, *Surgeon, United States Public Health Service*

This brief report was intended, primarily, to cover this subject as personally known to the writer at the United States Marine Hospital in Chelsea (Boston), Mass., for the period July 1, 1924, to June 30, 1927. However, as figures covering all hospital operation of the Public Health Service for the three fiscal years were easily available, it is deemed advisable to set forth all the data in a report separate from the annual reports of the service. In giving the figures bearing on these two causes for hospitalization, no comparison is made with former years, neither before nor after the eighteenth amendment went into effect, nor before more stringent efforts were made to curb the narcotic evil. Neither is any comparison attempted with figures from other hospitals during the same period. It is believed that anyone interested may easily make these comparisons.

In regard to the types of patients treated by the Public Health Service in its marine hospitals and in its many contract hospitals, it may be said that they are practically all adult males, usually between the ages of 18 and 50 years. No children of either sex are admitted, and women constitute much less than 1 per cent of all patients. In the service at large approximately 65 per cent of the persons hospitalized are from American merchant vessels; about 12.5 per cent are from the Coast Guard, while the remainder are from the Veterans' Bureau, United States Employees' Compensation Commission, and other Government services whose personnel are legally entitled to treatment by the Public Health Service. American merchant vessels and the Coast Guard furnish, it is seen, about 77.5 per cent of the patients. It is probably correct to say that 2.5 per cent of these represent officers of the two services, while the remaining 75 per cent—or three-fourths of all patients treated—are from the crews of merchant vessels and from the enlisted personnel of the Coast Guard. These men are usually employed at a reasonable wage and may be assumed to possess some money, for a time at least, after reaching port. It may be mentioned that it is with this personnel that tradition has long associated "hard drinking" and other forms of debauchery. Here again no comparison is attempted with other types of workers, but the figures seem to speak well for the "seamen."

In regard to the patients of the Marine Hospital in Chelsea (Boston), Mass., it may be said that there is a somewhat larger number of Coast Guard patients, the percentage there being at least 15, and seamen not less than 65 per cent. Incidentally, the opportunities for obtaining alcoholic drinks about the Chelsea water front are

probably not excelled at this time in any of our ports. The large foreign population has made difficult the enforcement of laws dealing with the manufacture and sale of alcohol.

TABLE 1.—*Alcoholism and drug addiction, United States Marine Hospital, Boston (Chelsea), Mass., July 1, 1924, to June 30, 1927*

Fiscal year	Patients treated (all causes)	Deaths (total)	Patients treated for alcoholism, acute and chronic	Deaths from alcoholism	Cases of drug addiction
1925	1,464	40	7	0	0
1926	1,567	38	5	1	0
1927	1,759	44	5	0	0
Total	4,790	122	17	1	0

Of the 17 alcholic patients treated at this hospital during the three years under consideration, all but two were men in their forties, most of them old alcoholics who were in for acute "exacerbations." The period of treatment was usually very short, seldom more than three or four days. There was no case of delirium tremens admitted to the hospital during this period, nor did such a case develop in any patient after admission. There were no cases of Korsakow's psychosis or acute alcoholic hallucinosis among the several psychotic patients sent for observation from the Marine Hospital to the Boston Psychopathic Hospital during the period under consideration. No patient was under treatment in this period for alcoholic multiple neuritis.

In the Marine Hospital at Chelsea there was, during these three years, one death attributed to cirrhosis of the liver. This patient had been a user of alcohol, but was also a syphilitic. It was the belief of the staff that the latter factor was the predominating one in this case. Of the two alcoholic patients under 40 years of age, one was the man who died in 1926. There was little to connect this case with alcohol. The immediate cause of death was complete suppression of urine, and the death certificate was given by the medical examiner to whom the case was referred because of a somewhat doubtful alcoholic connection.

No patient was treated for drug addiction in the Chelsea (Boston) Marine Hospital between July 1, 1924, and June 30, 1927. No such patient applied for admission. Further, it may be said that there was nothing which led to the belief that any patients treated during this period were using drugs or had used such in the past. No unusual desire for narcotics was noted in any postoperative case during this time.

TABLE 2.—*Alcoholism and drug addiction—Total for all marine hospitals for period July 1, 1924, to June 30, 1927*

Fiscal year	Patients discharged	Deaths (total)	Alcoholism, acute and chronic	Deaths from alcoholism	Cases of drug addiction
1925	31,908	879	240	1	30
1926	33,275	872	225	5	17
1927	33,531	901	283	1	8
Total	98,714	2,652	748	7	55

A comment that may be made on the above table is that the figures are based on "discharges" rather than "patients treated," as was the case in the table for the Chelsea marine hospital. This was necessary because of the method of preparing tables for the annual reports of the Public Health Service, but it is of no consequence.

In all marine and contract hospitals of the Public Health Service during the three-year period under consideration there were nine deaths reported as due to cirrhosis of the liver.

There are 25 marine hospitals operated by the service on the Atlantic, Pacific, Gulf, Great Lakes, and rivers of the United States. There are 125 contract hospitals—second, third, and fourth class stations—in the United States, Alaska, Hawaii, the Philippines, Porto Rico, Virgin Islands, and Canal Zone, where patients of the service are treated. These 150 hospital stations treated or discharged 748 patients in a period of three years who were victims of acute or chronic alcoholism.

The percentage of such patients varies slightly. For 1925 it is three-fourths of 1 per cent, for 1926 this dropped to two-thirds of 1 per cent, while for 1927 the percentage rose to a little more than four-fifths of 1 per cent.

The decline in cases of drug addiction—about 50 per cent for each year—is interesting, though no explanation is attempted.

Personal experience in the Marine Hospital in Chelsea leads to the remark that alcoholism and drug addiction present no problem of consequence there. Apparently the same is true for the other hospitals of the United States Public Health Service.

NATIONAL LEPER HOME (UNITED STATES MARINE HOSPITAL), CARVILLE, LA.

Review of the More Important Activities During the Fiscal Year Ended June 30, 1927

By O. E. DENNEY, *Surgeon (R), United States Public Health Service, Medical Officer in Charge*

The 12-month period here reported on has been especially satisfactory in that an increasing number of patients have shown gratifying progress toward permanent arrestment of leprosy. It is difficult, however, to measure this improvement in general health and morale,

and equally difficult to point to any one treatment or condition as being responsible.

During the year, 56 patients were admitted; 40 absconded; 12 absconders were readmitted; 2 patients were discharged on parole, leprosy arrested and as no longer a menace to public health; 1 leper was deported and several additional cases are receiving consideration by the Bureau of Immigration pending deportation; 103,337 hospital days of relief were furnished; and 17 deaths occurred, giving a mortality rate of 60 per thousand. The causes of death were as follows:

Mortality by cause

Arteriosclerosis, coronary	2	Pneumonia, bronchial, nephritis, acute parenchymatous	2
Cardiac asthma	1	Pneumonia, hypostatic	1
Enterocolitis (*Ameba histolitica*)	1	Pneumonia, lobar	3
Leprosy, mixed	1	Pneumonia, lobular, hypostatic	1

The hospital, as in the past, has been available for undergraduate and postgraduate instruction in leprosy. Ninety-three medical students, 110 physicians, and 32 nurses visited the hospital during the year. The Sixth Louisiana District Medical Society convened in the hospital for its annual session, and 92 physicians attended the meeting, which was devoted exlusively to the subject of leprosy. A demonstration of cases and a visit through the hospital followed the meeting.

Medical service.—During the year 191 patients were admitted to the infirmary from their regular quarters for the treatment of acute or chronic manifestations of leprosy. Twelve males and 8 females remained in the infirmary throughout the entire 12 months, while the remainder, after longer or shorter periods, returned to their regular quarters in the cottages, or died

Infirmary facilities are not completely satisfactory in that it has been necessary, in the absence of an infirmary building, to use cottages, with some remodeling, to furnish facilities for bed cases. The available bed space in the infirmary is always occupied. It has been necessary a number of times to place two beds in single rooms in order to accommodate lepers suffering from acute exacerbations of leprous symptoms. It should be noted that each patient in the institution has his private room in a cottage, which he retains during his temporary stay in the infirmary.

Plans have been drawn up and approved for the erection of a two-story, 100-bed infirmary building, in which can be satisfactorily housed the various important activities pertaining to patients acutely ill, simplifying the administration of the institution and rendering more efficient and economical the care of the patients. Congressional appropriation is necessary for the completion of this proposed infirmary building.

Of the 255 patients in the hospital, 154 are taking crude chaulmoogra oil by mouth, the dosage ranging from 3 drops to 400 drops daily, according to the tolerance of the individual. Twenty-eight patients have been placed on intramuscular injections of crude chaulmoogra oil, the oil, with an analgesic, being administered twice weekly in doses ranging from 3 to 8 c. c. This experiment, which will be reported in detail elsewhere, offers an opportunity to saturate the patient with chaulmoogra oil in what has so far proved to be a relatively painless manner. Previously reported chaulmoogra oil injections in this hospital and elsewhere have, of necessity, taken into consideration the considerable amount of pain from the injection of the preparations of chaulmoogra oil and its derivatives.

In the out-patient clinic, for the care of nonleprous Government employees and personnel, 381 patients were given emergency or routine treatment.

Surgical service.—During the year 70 surgical operations were performed, all of a relatively minor nature, extending in severity from the excision of ingrowing toenails to the excision of tumors. No deaths resulted from surgical procedures during the year. A total of approximately 75,000 surgical dressings were performed in the clinic for ambulatory lepers, under the supervision of the surgical staff. Fifty lepers are receiving experimental intravenous therapy, consisting largely of neosalvarsan, tryparsamide, and mercurochrome.

Recently, a group of advanced lepers was selected for experimental treatment by the intravenous injection of basic fuchsin, in increasing doses, with somewhat encouraging results to date.

Investigation in therapeutics.—Treatment has been continued with the ethyl esters of chaulmoogra oil augmented by the oral administration of the crude oil in specially formalized capsules. These latter seem to be resistant to the gastric juice; and the oil liberated in the intestines (and not in the stomach), does not provoke the same nausea and vomiting as when given in ordinary capsules.

A foreign protein is being used in two cases, in the hope that the reaction provoked may lead to improvement. The protein, an albumose (Hirudin), was selected because of its being a venom and also on account of its property of preventing the coagulation of blood. Reactions, febrile and cutaneous as well as local, have followed its use. Some clinical improvement has been noted in both cases, though neither has shown appreciable diminution in acid-fast organisms in lesions.

Special treatments.—It has been gratifying to note considerable improvement in contraction deformities of the hands and feet of those cases attending the clinic regularly for physiotherapy treatment. Ulcers have responded almost invariably with beneficial results from ultra-violet ray treatment. In many cases bone necroses have been arrested. Nerve pains have been relieved with the ultra-violet ray treatment and diathermy.

It has been interesting to note that nerve pains have responded more quickly to the ultra-violet radiations as secured from the carbon arc burner than to those from the quartz mercury burner. This may be due to the greater amount of heat given off by the carbon arc burner. Space in the physiotherapy and orthopedic department has become congested, due to the increase in number of patients applying for treatment and the additional necessary apparatus. Some of the patients have been relieved of their deformities, and sensation in many nerve cases has returned. Operations have resulted satisfactorily in all cases submitting to or applying for orthopedic operations. A total of 38,953 physiotherapy treatments were given during the year.

Neuropsychiatric service.—During the fiscal year 41 new patients and 56 old patients were examined in the neuropsychiatric section. Mental manifestations were noticed in 21 cases. All cases examined were of the mixed type of leprosy, but 24 showed marked neurological manifestations. Of the cases examined neurologically before being discharged on parole, none was found with active nervous symptoms. One patient passed through the episode of manic depressive psychosis which ran its course in about five months. To all appearances this patient is now normal. One patient showing hallucinations of sensation has markedly improved. One case presenting terminal dementia (praecox) died.

A paper on the mental aspects of leprosy was presented before the neurologic section of the American Medical Association at its annual session in Washington, D. C.

Ophthalmologic service.—The ophthalmologic problem for the past year has been the treatment of iridocyclitis; because its ultimate results if untreated, and often if treated, are lenticular and vitreous opacities and occlusion of the pupil. It is believed that mercury cyanide injected subconjunctivally has done some good.

Routine prophylaxis and treatment have been rendered to the group of patients who suffer considerably from both the acute and chronic ocular disorders.

Dental service.—Dental treatment has continued, directed largely toward the removal or prevention of pyorrhea, with routine treatment of leprous oral ulcers, diseased root canals, crown and bridge work, fillings, denture constructions, and prophylaxis.

Clinical laboratory.—The observation of certain clinical phenomena coincident with the vaccination of lepers with smallpox virus followed by more or less improvement in the patient (noted by Hopkins and Denney)[1] prompted the revaccination of lepers to determine the possibility of continuing this clinical improvement, presumably stimulated by vaccinia.

A single patient was first periodically vaccinated by subcutaneous and intramuscular injections of increasing doses of smallpox vaccine. The results were sufficiently encouraging to justify additional experimentation. At present 25 lepers with different clinical manifestations are receiving periodic subcutaneous or intramuscular injections of smallpox virus. A detailed report will be submitted at the appropriate time.

The knowledge that carbon-dioxide snow and some forms of cautery are useful in removing certain lesions of leprosy prompted one of the members of the staff to experiment with metallic applicators, heated to various temperatures by a current of water passing through the interior of the applicator. After experimentation a satisfactory de-

Tennis court

vice was obtained whereby the surface of an applicator is maintained at a controllable temperature, and gratifying results have been obtained in removing superficial leprous lesions. (Detailed report to be submitted.)

Experiments have continued in the isolation of acid-fast bacilli from lepers with the hope that some additional light might be shed upon the life history of the organism, which as yet does not appear to have been cultivated by routine methods.

A total of 7,868 routine examinations and cultures have been made in the laboratory by one full-time physician assisted by two patients who have been trained as technicians.

Clinical photography as a record of progress of individual patients has continued as a routine procedure. The majority of the photographs are in black and white, but a large number of records have been made by photographing leprous lesions in natural colors. The collection of photographic records is already very valuable and will become increasingly so.

Leprosy does not respect race, creed, or social status. A leprosarium hospitalizing patients from a large country cares for a cosmopolitan group seldom encountered in a general hospital. The manifold manifestations of leprosy, with the diversity of symptoms and the variety of psychologic responses coupled with the conscious or unconscious pessimism of the average human being suffering from a chronic progressive disease, confronts the administrative officers with the difficult problem of maintaining a proper morale.

Recognizing the great importance of occupation to prevent morbid introspection, vocational training has been introduced among the patients, in order that those physically and mentally able might be employed, to the profit of both the patient and the hospital.

In the current year, on the average, 81 lepers have been employed under the general designation "attendants." Many of this number gave daily and satisfactory service in their assigned work. The work performed by these employees is of a necessary nature requiring some skill and concentration, and ranges in variety from the more simple duties of housekeeping and bedside care of fellow patients to the more exacting work as assistants in the general laboratory, physiotherapy department, dental laboratory, and operating rooms. The compensation paid to the patients ranges from $15 to $45 a month per attendant. The work performed in many instances is equal in character to that to be expected from nonleprous employees, and the salary paid is probably half that which would be necessary to obtain nonleprous employees. Vocational training, therefore, furnishes daily routine occupation to one-third of the total population of the hospital and to almost all of those physically fit for such an undertaking.

The patients' library has continued its function of serving as a connecting link between the patients and the public. Yearly an increasing number of patients avail themselves of the books, magazines, and newspapers which are loaned under conditions similar to those existing in cities.

The technical library of the medical officer in charge is of great value to the hospital staff for direct study and for reference. The total number of volumes to date is 634. All the more important medical journals are subscribed for annually and bound.

A small golf course has been started on the patients' campus and a surprisingly large number of enthusiastic players has developed. A concrete tennis court was also constructed for the patients.

Routine maintenance and repairs of buildings and equipment have continued under the carpenters, plumbers, electricians, and painters. A repainting of all buildings on the reservation was begun in the latter part of the year, to continue until completion of the project.

Farming on a large scale was not so profitable as in previous years, due largely to flooding of crops by excessive rainfall and imperfect drainage, the rains being reinforced by excessive seepage from the Mississippi River during its flood season—a combination of conditions probably not to be encountered again for several years. The project, however, represents a credit balance of approximately $1,200.

The completion of the dairy barn has enabled the station to maintain a model dairy consisting of 74 milk cows. In addition, 68 beef cattle have been received from the United States Marine Hospital at Fort Stanton, N. Mex., and fattened preparatory to slaughtering. The dairy herd, consisting of 20 Jerseys and 54 Holsteins of good stock, produced 47,277 gallons of excellent milk having a total market value of $19,856.34. The entire herd has been repeatedly registered as nontuberculous.

With materials furnished by the supervising architect and with station labor, a reinforced concrete three-room isolation building has been constructed for the segregation of dangerously insane or other patients whose liberty might endanger themselves or their fellow patients.

A fire-resisting garage has also been constructed by station labor, of size sufficient to house 15 trucks and 3 cars. A large workshop with galvanized-iron walls and doors is a part of the building.

The administration building is being enlarged by adding an additional kitchen and dining-room facilities on the first floor, for the personnel, and an additional dormitory and infirmary space on the second floor.

An artesian well was drilled immediately adjoining the power house in order to obtain cool water for the ammonia condensers of the ice plant. A flowing well was obtained, delivering water without

pressure. The amount was increased by the installation of an air lift. The water delivered to the condensers is at a temperature of 68° F., as compared with the summer reservoir temperature of from 80° to 96° F. The water contains a large amount of iron and sulphur and therefore is not suitable for general use upon the station.

During the year changes were made in the method of water clarification and purification by the discontinuance of alum precipitation and the substitution of iron and lime. The chemicals are let into the water intake by mechanical feeders and mixed by passing rapidly by baffles before sedimentation. A crystal-clear water, bacteriologically satisfactory, is obtained after final filtration through three sand-gravel filters.

In the spring of 1927 a gradual rise of the Mississippi River, upon which this hospital faces, forboded considerable damage to the surrounding country, and it was necessary, for a period of approximately six weeks, for the hospital to assume its share of the neighborhood's work in maintaining the levees in a safe condition. The hospital, by agreement, was assigned the responsibility of maintaining nearly 3 miles of levee, and the day laborers, carpenters, painters, and even members of the technical staff, cheerfully cooperated with the levee officials.

Routine work on the station was, of necessity, almost abandoned beyond the necessary care of patients and sanitation, with coincident setback to the general maintenance of the reservation. As the river subsided, routine work was resumed and the grounds are rapidly being returned to their normally neat and orderly appearance.

KEY-CATALOGUE OF INSECTS OF IMPORTANCE IN PUBLIC HEALTH

The United States Public Health Service has just issued Hygienic Laboratory Bulletin No. 150, entitled "Key-Catalogue of Insects of Importance in Public Health." This represents the fourth catalogue in this series of key-catalogues on medical zoology issued by the Public Health Service.

The work has been prepared by Prof. C. W. Stiles of the United States Public Health Service, and Dr. Albert Hassall of the United States Bureau of Animal Industry, on the basis of their personal observations combined with thousands of references to the literature indexed in the Government card catalogue.

Ordinarily, insects in their relation to health and disease are viewed chiefly from the standpoint of being either external parasites, such as lice and fleas, or transmitters of disease, such as mosquitoes in the case of malaria and fleas in the case of bubonic plague. The present

publication carries the subject much more into detail. In the body of the bulletin numerous insects are arranged systematically according to their more or less generally adopted classification, with notation as to their public health importance and their geographic distribution. In the introduction, the different genera of insects are cross referenced to the following subjects:

A, biting insects; *B*, on cadavers or in graves; *C*, control of public-health pests; *D*, dermatology (lesions, dermatitis, eruptions, exanthema, parasites, urticaria); *E*, edible (food, drink); *F*, excreta; *G*, food and drink; *H*, jurisprudence; *I*, laity (fear, superstition); *J*, parasites and pseudoparasites (abdomen, ear, external, eye , head, intestine, miscellaneous, mouth, nose, stomach, subcutaneous, throat, urinary system); *K*, pests (books, clothes, drugs, records, miscellaneous); *L*, pinching insects; *M*, poisons (arrows, defensive, food, spines, miscellaneous); *N*, pollution (air, water); *O*, stinging insects; *P*, therapeutics (lay, professional); *Q*, vectors (aspergillus, bacteria, filth, Protozoa, Trematoda, Cestoda, Nematoda, Acanthocephala, Insecta).

The publication is of special interest to public health officers, physicians, zoologists, lawyers, and students of medicine and zoology, and forms a condensed summary of the entire field of public health entomology.

For instance, if a public health officer wishes to know what particular insects are known to transmit or are suspected of transmitting a given infectious disease, he refers to the name of this disease in the introduction and then follows the subject as cross referenced to the body of the work. If a dermatologist wishes to locate the various caterpillars which cause the condition known as urticaria, he looks up the word "urticaria" in the introduction under Dermatology, and finds cross references to 40 different genera of moths and butterflies, the larval stages of which cause urticaria in man. If a lawyer desires to find a list of the insects of importance in zoological jurisprudence, as, for instance, in connection with the Law of Nuisances, or in connection with the French theory of determining how long a human body has been dead, he looks for the word "jurisprudence" in the introduction and finds the subject cross referenced to the body of the work. In connection with the application of entomology to legal cases involving possible homicide, the authors of this bulletin take a very conservative position toward the French theory; in fact, they state that it is of very limited, if any, practical application.

Copies of this bulletin may be obtained upon request from the Surgeon General, United States Public Health Service, Washington, D. C.

UNDULANT FEVER IN NEW YORK STATE

The following item relative to the occurrence of undulant (Malta) fever and the prevalence of contagious abortion in cattle in New York State was taken from the Health News for March 26, 1928, published by the New York State Department of Health:

From January 1, 1926, to date there have come to the attention of this department 24 cases of undulant fever. Four additional reported cases are considered somewhat doubtful because of inadequate history or absence of laboratory confirmation.

Of the 24 cases one was an infection by *B.* [*Br.*] *melitensis* acquired in the State laboratory and without doubt was a true case of Malta fever. The others were probably all caused by *B.* [*Br.*] *abortus*, as agglutination of that organism occurred with a higher dilution of the patient's serum than *B.* [*Br.*] *melitensis*.

There was one definite outbreak of undulant fever in Newark, Wayne County, although only three persons were affected. The patients were of different families but all were using grade A raw milk from the same farm on which five cows had aborted. It was found at the State Agricultural College at Cornell that the blood serum from these cows agglutinated *B.* [*Br.*] *abortus* in high dilution.

In addition to this small outbreak there have been two cases reported from each of the following cities: Jamestown, Ithaca, Hudson, and Utica, with an additional case from just outside the last-named community. These were all solitary cases, as were the remainder of the reported cases which were widely spread over the State.

With the exception of the Newark, N. Y., outbreak the epidemiological evidence is not very conclusive of the relationship of milk to the means of transmission. On the other hand, it is stated that contagious abortion is very prevalent in New York State, 30 per cent of the herds being estimated as affected.

DEATHS FROM AUTOMOBILE ACCIDENTS IN LARGE CITIES, FEBRUARY 28, 1926, TO FEBRUARY 25, 1928

The Department of Commerce announces that during the four weeks ended February 25, 1928, automobile accidents were responsible for 510 deaths in 77 large cities of the United States, as compared with 441 deaths during the four weeks ended February 26, 1927. Most of these deaths were the result of accidents which occurred within the corporate limits of the city, although some accidents occurred outside of the city limits.

For comparison, the number of deaths due to automobile accidents within city limits is desirable. Such figures are available for 75 cities for the four-week period ended February 25, 1928, and for the corresponding four-week period of 1927, the figure for 1928 being 448, as contrasted with 384 for the corresponding four weeks in 1927.

The numbers of automobile fatalities by four-week periods since May, 1925, for 77 cities, regardless of place of accident, are given below. The lowest total (346) appears for the four-week period

ended March 27, 1926, and the highest (686) for the four-week period ended November 5, 1927. The numbers in the 37 periods of four weeks were as follows:

Four weeks ended—

February 25, 1928	510	February 26, 1927	441	February 27, 1926	374
January 28, 1928	528	January 29, 1927	470	January 30, 1926	428
December 31, 1927	623	January 1, 1927	522	January 2, 1926	550
December 3, 1927	618	December 4, 1926	632	December 5, 1925	623
November 5, 1927	686	November 6, 1926	676	November 7, 1925	612
October 8, 1927	662	October 9, 1926	650	October 10, 1925	527
September 10, 1927	526	September 11, 1926	558	September 12, 1925	521
August 13, 1927	506	August 14, 1926	499	August 15, 1925	467
July 16, 1927	573	July 17, 1926	482	July 18, 1925	493
June 18, 1927	504	June 10, 1926	547	June 20, 1925	492
May 21, 1927	529	May 22, 1926	493	May 23, 1925	421
April 23, 1927	491	April 24, 1926	423		
March 26, 1927	439	March 27, 1926	346		

For the 52-week periods ended February 25, 1928, and February 26, 1927, the totals for the 77 cities were, respectively, 7,196 and 6,740, which indicate a rate for the latest period of 22.4 per 100,000 population, as against an earlier rate of 21.3, or an increase of 5 per cent in the rate in a single year.

Ten cities reported no deaths from automobile accidents for the last four weeks, while eleven cities reported no deaths from automobile accidents for the corresponding period of 1927.

For the last four-week period reports as to whether deaths occurred from automobile accidents within city limits or outside were received from all of the 77 cities reporting. In these cities, the total number of deaths from automobile accidents in this four-week period was 510, but only 450 of these were due to accidents within city limits.

COURT DECISION RELATING TO PUBLIC HEALTH

Ordinance requiring milk sold for consumption on premises to be in original container held valid.—(Wisconsin Supreme Court; City of Milwaukee *v.* Childs Co., 217 N. W. 703; decided February 7, 1928.) An ordinance of the city of Milwaukee provided:

It shall be unlawful, for any person, within the limits of the city of Milwaukee, to sell milk in any way whatsoever for consumption on the premises where sold, excepting in original containers well capped or sealed, served intact in such container or opened in the presence of the person served, and containing only the quantity of milk intended for use of the person served, and all milk so served shall, in every instance, be bottled either at a dairy or milk plant.

The defendant was convicted of serving milk to a patron of its restaurant in violation of the terms of the ordinance. On appeal the power of the city to adopt the ordinance was challenged and the ordinance itself was attacked as being invalid, but the supreme court affirmed the conviction. The following are portions of the appellate court's opinion:

The ordinance, if reasonable, is well within the power of the city to enact. Properly construed, the ordinance is a reasonable regulation. The language of the ordinance would authorize a very sweeping construction—a construction which would make it impossible to serve any article of food of which milk was the dominant element, such as milk toast, an oyster stew, or milk to be used in tea or coffee, or upon pudding or fruits or breakfast foods. To give the ordinance such a construction would make the reasonableness thereof very doubtful, and we are disposed to construe it as prohibiting merely the sale of milk for beverage purposes except as therein prescribed. As so construed, the regulation is not unreasonable.

It is a matter of common knowledge that milk is a prolific source of disease and that it is easily contaminated. Every regulation relating to the handling of milk which minimizes the opportunity for contamination is promotive of the health of the community. The regulation provided by the ordinance in question certainly has that effect. * * *

The contention that the ordinance denies due process of law and deprives defendant of property without compensation is not of sufficient substance to require discussion. The police power of the State with reference to such matters is too well settled to justify extended treatment here. [Cases cited.]

Neither is there any room for the claim that the ordinance was not violated as a matter of fact. The evidence shows that the milk served was dipped from a larger container in the kitchen and carried to the patron. It may be that the defendant handled the milk served in its restaurant in a highly sanitary manner, but that constitutes no defense. Because milk is customarily handled in a manner which affords opportunity for contamination, the municipality is justified in prescribing regulations for the handling of milk in a manner which shall avoid opportunity for such contamination. Such regulations when so prescribed must be observed by those dealing in milk. The dealer can not justify noncompliance with such regulations by asserting that his method of handling milk was just as sanitary as the regulations prescribed by the municipality. It is possible that, if all dealers handled milk as defendant did, there would be no necessity for the ordinance. But the fact that many dealers do not observe sanitary methods in handling milk makes such regulations necessary or proper. When such regulations are prescribed, they must be observed by all, by the considerate as well as by the inconsiderate dealer.

PUBLIC HEALTH ENGINEERING ABSTRACTS

Bacteriological and Parasitological Study of the Night Soil Disposal in Japan. R. Takano, *Journal Public Health Association of Japan*, vol. 3, No. 12, December, 1927, pp. 1–10. (Abstract by N. R. Stoll.)

This is evidently a continuation of studies earlier published in the same journal in February and March, 1927. Both typhoid bacilli and parasite eggs were examined for longevity under storage conditions in typical night soil jars and a newly devised privy. Using the jars which are typical in the privies of Japanese houses, having a depth of 1.5 feet, a diameter of 1.8 feet, and a capacity of 60 to 100 liters, they were filled with night soil taken from the privy of a representative house. Then a culture of the typhoid bacillus was mixed at the ratio of 1½ mg. per 100 c. c. of night soil, and materials for culture test were then removed on later days from the upper, middle, and lower layers of the contents of the jars. There was a marked correlation with temperature as to the longest intervals during which viable typhoid bacilli were recovered. (Data as to differences at different levels of the night soil are not given.) Thus in fall and winter at Tokyo,

when the maximum temperature in the receptacles was 14° to 19° C., typhoid bacilli were recovered up to 183 days (in 18 experiments a mean of 121 days); in spring, at maximum receptacle temperatures from 19.5° to 24° C., up to 47 days (in 10 experiments a mean of 29 days); in summer, at maximum receptacle temperatures from 25° to 27° C., up to 11 days (in 9 experiments a mean of 8 days).

Experiments in similar receptacles were carried on with *Ascaris* and hookworm eggs. The *Ascaris* perished most speedily in summer, although it takes three months at the shortest. Hookworm eggs do not grow, and they perish by degrees in summer in about one month. These tests were made on the basis of the last occasion when a viable egg could be demonstrated.

The author then tested out the newly devised privy (a modified septic tank arrangement) with five compartments. While typhoid bacilli could always be demonstrated in the first chamber, they decreased markedly in the successive chambers, the fifth chamber being negative except for a very few organisms during the winter. With *Ascaris* and hookworm eggs, the third, fourth and fifth chambers were always negative for viable eggs. The author believes his laboratory tests, together with actual use of the privy, demonstrates the feasibility of the recommended privy for use by farmers who wish to use the night soil from the fifth chamber for fertilizing fields. Chemical tests showed no loss of nitrogen in the fifth chamber contents.

Studies on the Infectivity of Plasmodia of Birds for Mosquitoes, with Special Reference to the Problem of Immunity in the Mosquito. Clay G. Huff. *American Journal of Hygiene*, vol. 7, No. 6 November, 1927, pp. 706-734. (Abstract by A. L. Dopmeyer.)

The contents of this article are as follows: I. Introduction. II. Infectivity and transmission experiments with culicine mosquitoes: (*a*) Historical; (*b*) materials; (*c*) methods; (*d*) results of dissection; (*e*) transmission experiments; (*f*) discussion. III. A study of immunity in the mosquito. IV. Observations upon the biology of mosquitoes. (*a*) Biting habits; (*b*) breeding habits; (*c*) survival under laboratory conditions. V. Observations upon the parasites: (*a*) Prepatent periods; (*b*) sizes of oocysts; (*c*) location of oocysts; (*d*) course of infection with respect to gametocytes; (*e*) figures. VI. Summary. VII. Literature cited.

The summary is as follows: (1) Two species of mosquitoes (*Culex territans* and *salinarius*) are reported for the first time as susceptible to infection with three species of *Plasmodium* of birds (*cathemerium*, *praecox*, and *inconstans*); (2) *Culex pipiens*, previously known as a vector of at least one species of *Plasmodium*, was found to be a vector of two of the three species and susceptible to infection with the other; (3) *Culex quinquefasciatus* and *Aedes aegypti*, previously known as vectors of one species, were found to be susceptible to two of these species of *Plasmodium*. Although no infections of these two species of mosquitoes were obtained with the third species of parasite, it does not seem advisable to conclude that they are nonsusceptible to it until a larger number of feedings have been made; (4) negative results were obtained from infectivity experiments with six species of *Aëdes* and one of *Anopheles* against two of the parasites; and with one species of *Psorophora* against one of the species of parasite; (5) complete transmission of one of the species of parasite was effected with *Culex salinarius;* (6) the length of life of the asexual stages of the parasite in the stomachs of both *Culex pipiens* and *Aëdes sollicitans* was between five and six hours; (7) the digestion of red cells in the stomachs of *C. pipiens* and *A. sollicitans* required about the same amount of time; (8) the asexual stages entirely disappeared from the stomach of *C. pipiens* in six hours, but could be found, though altered in appearance, in *A. sollicitans* in the twentieth hour. Ookinetes first appeared in each species at the end of the twelfth

hour and remained at least 20 hours in *A. sollicitans* and 39 hours in *C. pipiens;* (9) the hypothesis that differences in digestion in *Culex pipiens* and *Aëdes sollicitans* play an important rôle in immunity and susceptibility of mosquitoes is abandoned; (10) evidence indicating an individual immunity within a susceptible species is presented; (11) decided differences in the biting habits of the mosquitoes used were found. In view of preferences shown by *Culex pipiens,* it is believed that this species is the principal vector in nature. Seven species of mosquitoes (representing seven genera) consistently refused to feed from canaries. Marked differences in the reactions of the birds to the bites of the various species were noted; (12) three generations of *Culex pipiens* were reared in captivity; (13) significant differences were found in the length of the prepatent periods of all three species of the parasites; (14) in two typical primary infections in birds the percentage of gametocytes was found to rise continuously from the time of their appearance. The maximum number of gametocytes occurred one or two days after the maximum of total parasites. The percentage of gametocytes in relapse is much lower than in the primary infection. The appearance of symptoms approximately upon the day when the number of gametocytes is at its maximum, is thought to be a factor in the epidemiology of transmission; (15) a study of the distribution of the number of gametocytes over a 24-hour period shows no periodicity similar to that found in the asexual forms.

Studies on Brazilian Mosquitoes. III Genus Culex. Francis Metcalf Root. *American Journal of Hygiene,* vol. 7, No. 5, September, 1927, pp. 574–598. (Abstract by A. L. Dopmeyer.)

This article is the third of a series presenting results obtained during a trip to Brazil in 1925, and consists of a description of various species of *Culex* mosquitoes found, together with a number of plates illustrating the characteristics of these mosquitoes.

The description includes nine species under the subgenus *Culex;* one under the subgenus *Melanoconion;* one under the subgenus *Aëdinus;* seven under the subgenus *Microculex;* twelve under the subgenus *Choeroporpa;* and two under the subgenus *Mochlostyrax.*

Studies on Brazilian Mosquitoes. IV. Notes on Some Brazilian Species of Anopheles. Francis Metcalf Root. *American Journal of Hygiene,* vol. 7, No. 5, September, 1927, pp. 599–605. (Abstract by A. L. Dopmeyer.)

This article is the fourth of a series presenting results obtained during a trip to Brazil in 1925, and consists of descriptions of various species of *Anopheles* mosquitoes found, as follows: (I) The *Myzorhynchella* group; (II) *Anopheles mediopunctatus* Theo; (III) *Anopheles eiseni* Coquillet; (IV) *Anopheles fluminensis* new species.

Several plates are shown illustrating the physical characteristics of the mosquitoes described.

A Comparative Study of the Early Larval Stages of Some Common Flies. Shan Ming Tao. *American Journal of Hygiene,* vol. 7, No. 6, November, 1927, pp. 735–761. (Abstract by A. L. Dopmeyer.)

This article is a report on a detailed study of the early stages of some flies which are common visitors to dwelling places, with keys to some common genera of the families Calliphoridae, Muscidae, Anthomyidae, and Sarcophagidae. Brief descriptions of each species studied are given for the two larval stages.

In his conclusion the author states that he wishes to emphasize the fact that there are distinct generic differences and possibly specific differences between the common carrion and filth flies in their early larval stages.

There is also a bibliography and a number of plates for illustration.

Mosquito-proof Gutterings. F. G. Cawston. *Journal Royal Army Medical Corps*, vol. 49, No. 6, December, 1927, p. 441. (Abstract by Harriet S. Ryan.)

All roof-guttering has been excluded from houses in the Panama Canal Zone and other tropical places after attempts to secure a roof-guttering which will not encourage the breeding of mosquitoes. Cast-iron gutterings could be used to advantage if they were made in molds 5 inches in diameter with a depth of the gutter increasing toward the outlet for the water. The section area should increase as the catchment area and volume of water increase toward the down-pipe. By fixing the upper edge of the guttering on a horizontal plane the required slope is attained; and where a down-pipe is fixed to allow a drop from each end of the roof, a fall of even 2 inches from each end of a 48-foot wall is not too great. Sheet-iron guttering cut out with converging borders, 2 inches wider at one end than at the other end of a 6-foot piece, when bent so that its edges are parallel, gives a slope of 1 inch in every 6 feet. A slope of only 1 inch in 24 feet is considered sufficient for larger buildings.

Sterilization of Milk by Impact of Steam. G. E. Grindrod. (Creamery and Milk Plant Mo., 16 (1927), No. 9, pp. 38, 40, 42, 44, 46.) *Experiment Station Record*, U. S. Department of Agriculture, vol. 58, No. 2, February, 1928, pp. 169–170.

"A general discussion of the steam impact principle of sterilization, including the theory of the process, the method of application, and its effect on various products and the results obtained by it on various milk products. Under proper conditions this new method renders a mass of milk or cream completely sterile by exposure for one minute at 230° F."

The Accuracy of Bacterial Counts from Milk. Robert S. Breed. *American Journal of Public Health*, vol. 17, No. 6, June, 1927, pp. 604–606. (Abstract by F. R. Shaw.)

The author points out that the word "count" in this connection is a misnomer and that the results of ordinary laboratory procedure are not infrequently used in a manner to suggest greater accuracy than is warranted, and that sometimes injustices in the grading of milk result from too fine a distinction. The "count" is, in reality, an "estimate," and its value is dependent upon the relative accuracy of the work. Emphasis is placed upon the importance of checking the accuracy of the estimates by one method of counting bacteria, by making duplicate estimates by one or more different methods.

It is pointed out that the cause of the greatest inaccuracies in agar plate counts is due to the existence of clumps of bacteria in milk—these clumps containing 2, 4, 6, 8, or even 25 to 30 individual bacteria. In view of this, the former practice of determining accuracy by agar plate counts on a series of samples or by different analysts is not considered of great value. There has occurred during recent months the unfortunate resurrection and broadcasting of past literature which cites unjustified conclusions regarding the accuracy of plate counts.

The author cites the studies of the New York Experimental Station in having "prepared samples of milk" examined by six analysts in two laboratories by the methods of group count, agar plate count, and individual bacteria count. The samples of milk containing the *B. coli* were prepared in such a way that the final counts were expected to be in the ratio of 1 : 2 : 4. The laboratory findings were remarkably close to these in each method of counting that was used. A point of particular interest is that the agar plate counts were intermediate between the group and individual bacteria microscopic counts.

Avoiding Pollution by Coke Oven Wastes. Hugh E. Jones. *Water Works Engineering*, vol. 81, No. 3, February 1, 1928, pp. 141–142 and 178. (Abstract by Chester Cohen.)

Phenol, or carbolic acid, is a product of destructive distillation of coal, and is present to the extent of less than one-half of 1 per cent in the ammonia liquor which condenses out of raw coke-oven gas. In the process of lime treatment of this ammonia liquor, the phenol combines to form calcium phenolate which passes into the sewers as still waste. Subsequent action of acids and carbon-dioxide in the water reduce the calcium phenolate to phenol which, in the event of subsequent chlorine sterilization of the water, produces the pronounced and disagreeable chlorophenol taste.

Investigations in late years have attempted to remove the phenols prior to the lime treatment. Two successful methods were evolved; namely, the benzol extraction method and the patented Tiddy-Hoffner, or distillation, method. Description of the first method is given, together with sketch of process and accompanying formula and reactions. Through operation of this benzol extraction method, the extraction efficiency has been raised over 96 per cent. More than 25,000 gallons of pure phenol are recovered yearly from the 36,000 gallons of ammonia liquor treated daily. The plant is financially self-supporting.

Creamery Waste Treatment. Elton D. Walker. Proceedings of the First Conference of Sewage Works Operators, Pennsylvania State College, July 13–14, 1926, Tech. Bulletin No. 1, pp. 49–53. (Abstract by J. B. Harrington.)

The writer of this article describes the trouble experienced in treating creamery wastes at the Pennsylvania State College sewage disposal plant, consisting of a screen chamber, in Imhoff tank, a trickling filter, chlorine disinfection, two settling basins, and two sludge beds. The creamery wastes when turned into the disposal plant caused an acid condition to exist. Proper digestion was not taking place, and the sludge was yellow, with a foul odor. When the acid condition was neutralized by lime, digestion again became active. More difficulty was experienced in checking the growth of *Oospora lactis* and *Leptomitus* on the inside of the sewer pipe. During the summer, strips of an inch or more in thickness and up to 30 feet in length would break loose clogging the screen, pipes, and nozzles at the plant. Tests were then made to determine the food of *Oospora lactis.* From these tests it was concluded that this organism grows most rapidly when lactic acid is present in amounts varying from 200 to 600 p. p. m. The next step was to determine the potential lactic acid in the creamery wastes and the amount of hydrated lime necessary to neutralize it. Treatment apparatus consisted of an oil barrel with two jets nearly tangential to a conical bottom. When necessary to clean the sewer, heavy doses of bleach were used.

Contact Beds. C. A. Emerson, jr. Proceedings of First Conference of Sewage Works Operators, Pennsylvania State College, July 13–14, 1926, Tech. Bulletin No. 1, pp. 37–38. (Abstract by J. B. Harrington.)

The construction and action of contact beds are explained, and the history of the development of this type of sewage treatment are briefly summarized. The physical appearance of the effluent is noted, as is the relative efficiency of fine grained and coarse grained beds. Contact beds require more head and produce less odor than trickling filters, and have their greatest usefulness in the field of small communities and institutions. It appears unlikely that they will be used for large cities, clogging and high construction costs being their chief disadvantages.

Sewage Treatment Works at Holland, Michigan. Paul Hansen and K. V. Hill. *The American City*, vol. 38, No. 1, January, 1928, pp. 168, 170. (Abstract by C. R. Cox.)

The sewage from Holland was formerly discharged without treatment into Black Lake, and, as a result, the lake was seriously polluted. This detracted from the value of the lake for recreational purposes, so the city authorities decided

to install a treatment plant to improve conditions. Tannery wastes also add to pollution, but a separate treatment plant is advocated for these wastes.

The disposal works consist of grit chamber, bar screens, pumping station, Imhoff tanks, chlorination apparatus and chlorine contact tank, and sludge beds. Provisions are made to add trickling filters at a future date if this is found desirable. Detention in Imhoff tanks is about three hours, with estimated future flow of 100 gallons per capita for a population of 22,500. Sludge digestion capacity is 2.6 cubic feet per capita. Sludge beds have area of 0.72 square feet per capita. Beds were to be inclosed in glass, but lack of funds prevented this.

Trickling Filters. Robert Hall Craig. Proceedings of the First Conference of Sewage Works Operators, Pennsylvania State College, July 13–14, 1926, Tech. Bulletin No. 1, pp. 39–41. (Abstract by J. B. Harrington.)

The trickling filter is a later development in sewage treatment than the contact bed, as the result of the demand for plants with a greater capacity per unit area. The advantages and disadvantages of trickling filters as compared with contact beds are briefly compared as follows: (1) Greater capacity per unit area; (2) a more complete nitrifying action in the trickling filters and a more stable effluent; (3) the chief disadvantage of trickling filters is the increased head (4 to 6 feet) necessary for operation.

Six rules of operation pertaining to the siphon dosing chamber, nozzles, ponding or pooling, testing of effluent, underdrains, and sprinkling pipe system are described briefly. Odors may be reduced by increasing the size of the spray and by the careful use of bleach.

Water Pollution in Louisiana. Percy Viosca, jr. Trans. Am. Fisheries Soc. 56, 101–7 (1926). Abstract by Edward Bartow in *Chemical Abstracts*, vol. 22, No. 4, February 20, 1928, p. 651.

"Oil pollution of streams in Louisiana, including H_2SO_4 from the refineries and salt from wells, has been lessened by oil traps and by the reuse of the acid. Pollution by paper-mills wastes is decreased by removal of pulp and oxidation in shallow ponds. Pollution by sugar-mill wastes is lessened by settling basins, where sedimentation and biological action take place. Pollution by gravel-washing plants can be prevented by keeping the clay and sand out of the rivers. Pollution by city sewage may be taken care of by extending the sewers to deep water."

Cannery Waste Disposal. A. Elliott Kimberley. *The Canner* 66, Serial No. 1717, 18–21 (1927). Abstract by Carl R. Fellers in *Chemical Abstracts*, vol. 22, No. 4, February 20, 1928, p. 656.

"Studies are reported on peas, green beans, lima beans, corn, succotash, and tomatoes. The attempt has been made so to modify cannery waste by oxidation that its powers of pollution are most substantially reduced. Data are presented on the units of pollution in terms of stream demand per day by screened wastes from representative packs and corresponding minimum stream flows required to prevent nuisance and to conserve fish life."

DEATHS DURING WEEK ENDED MARCH 24, 1928

Summary of information received by telegraph from industrial insurance companies for the week ended March 24, 1928, and corresponding week of 1927. (From the Weekly Health Index, March 28, 1928, issued by the Bureau of the Census, Department of Commerce)

	Week ended March 24, 1928	Corresponding week 1927
Policies in force	70, 702, 349	67, 112, 016
Number of death claims	14, 519	13, 742
Death claims per 1,000 policies in force, annual rate	10. 7	10. 7

Deaths from all causes in certain large cities of the United States during the week ended March 24, 1928, infant mortality, annual death rate, and comparison with corresponding week of 1927. (From the Weekly Health Index, March 28, 1928, issued by the Bureau of the Census, Department of Commerce)

PLAGUE-PREVENTION WORK IN THE UNITED STATES

Seattle, Wash.—The report of rat-trapping operations of the United States quarantine station at Seattle for the month of February, 1928, shows a total of 927 rodents taken and 288 examined during the month. None was reported plague-infected.

Los Angeles, Calif.—The rodent division of the Los Angeles Board of Health reports 5,924 rodents collected, and 3,536 examined during the six weeks from February 5 to March 17, 1928. None was found plague-infected.

California.—The weekly reports of plague-suppressive measures in California during the nine weeks from January 8 to March 10, 1928, show a total of 6,417 rodents received and 5,362 examined during the period. Six ground squirrels were reported as plague-infected February 25 to 28, 1928, in Santa Cruz, Calif. The last case of human plague was reported as occurring on February 9, 1928, at Santa Cruz.

GENERAL CURRENT SUMMARY AND WEEKLY REPORTS FROM CITIES

The 98 cities reporting cases used in the following table are situated in all parts of the country and have an estimated aggregate population of nearly 31,500,000. The estimated population of the 93 cities reporting deaths is more than 30,875,000. The estimated expectancy is based on the experience of the last nine years, excluding epidemics.

Weeks ended March 17, 1928, and March 19, 1927

	1928	1927	Estimated expectancy		1928	1927	Estimated expectancy
Cases reported				*Cases reported*—Contd.			
Diphtheria:				Typhoid fever:

Smallpox:							
42 States	1,335	1,097					
98 cities	126	182	132				

City reports for week ended March 17, 1928

The "estimated expectancy" given for diphtheria, poliomyelitis, scarlet fever, smallpox, and typhoid fever is the result of an attempt to ascertain from previous occurrence the number of cases of the disease under consideration that may be expected to occur during a certain week in the absence of epidemics. It is based on reports to the Public Health Service during the past nine yrs. It is in most instances the median number of cases reported in the corresponding week of the preceding years. When the reports include several epidemics or when for other reasons the median is unsatisfactory, the epidemic periods are excluded and the estimated expectancy is the mean number of cases reported for the week during nonepidemic years

If reports have not been received for the full nine years, data are used for as many years as possible, but no year earlier than 1919 is included. In obtaining the estimated expectancy, the figures are smoothed when necessary to avoid abrupt deviations from the usual trend. For some of the diseases given in the table the available data were not sufficient to make it practicable to compute the estimated expectancy.

Division, State, and city	Population, July 1, 1926, estimated	Chicken pox, cases reported	Diphtheria: Cases, estimated expectancy	Diphtheria: Cases reported	Influenza: Cases reported	Influenza: Deaths reported	Measles, cases reported	Mumps, cases reported	Pneumonia, deaths reported
